Al-Zn-Mg-Cu (AA7050) aluminium alloy

 $\eta$ -type precipitates

Layer-by-layer growth

 $\eta_4'$  and  $\eta_{12}$  precipitates

## ABSTRACT

Using high-angle-annular-dark-field (HAADF) scanning-transmission-electron microscopy (STEM), we have investigated  $\eta$ -precipitates in the Al-Zn-Mg-Cu (AA7050) aluminium alloy. The HAADF STEM images taken along the zone axes of  $[10\bar{1}0]\eta$ ,  $[1\bar{2}10]\eta$ , and  $[0001]\eta$  illustrated the projected atomic-scale configurations of  $\eta$ -MgZn<sub>2</sub> crystal. The precipitates developed in layer-by-layer growth, supplied with precursors such as Zn, Cu, and Mg, which were solute atoms segregated around the  $\eta$ /Al interfaces due to the higher lattice strain energy. Stacking faults and defect layers composed of flattened hexagons were frequently observed along the zone axes of  $[1\bar{2}10]\eta$  and  $[10\bar{1}0]\eta$ , respectively, and their formation was elucidated, similarly taking into account the layer-by-layer growth. Occasional coalescence between two precipitates yielded a complicated boundary or a twin-like boundary. Based on the differences in orientation relationships between  $\eta$ -types and the Al matrix reported to date, two new types of  $\eta$  precipitates have been recognized and named  $\eta_4'$  and  $\eta_{12}$ .

## 1. Introduction

The lightweight AA7050 (Al-Zn-Mg-Cu) aluminium alloy possesses high strength owing to precipitate hardening [1]. The precipitation sequence for such aluminium alloys has been reported [1–17] as follows: super-saturated solid solution (SSSS) → GP zones (GP I and II [2–6]) →  $\eta'$  precipitates (4 variants [2,7–10]) →  $\eta$  precipitates (11 types,  $\eta_1$ – $\eta_{11}$  [1,2,7,8,11–15]). Recently, Chung et al. [7], who identified GPII zones,  $\eta'$ , and  $\eta_2$  precipitates in AA7050 aluminium alloy by high-resolution transmission electron microscopy (HRTEM), have elucidated the transition mechanisms of GPII zone →  $\eta'$  precipitate and  $\eta'$  precipitate →  $\eta_2$  precipitate. Bendo et al. [11], Marioara et al. [18], and Xu et al. [19] have analyzed the stacking structures in the  $\eta_1$  and  $\eta_2$  types on the atomic scale by Cs-corrected high-angle annular-dark-field (HAADF) scanning-transmission electron microscopy (STEM). However, the structures and the growth mechanisms of  $\eta$ -type

precipitates on the atomic scale have not yet been completely elucidated.

The  $\eta$  phase possesses the space group of  $P6_3/mmc$ , and its stoichiometric composition in the equilibrium state is normally approximate to that of MgZn<sub>2</sub>, which is known as a hexagonal C14 Laves phase in the Al-Zn-Mg-Cu aluminium alloys [1,2,7,11,12,14,16]. Generally, Laves phases exist in three fundamental structures: hexagonal C14, cubic C15 and dihexagonal C36 structures [20,21]. In these structures, they follow the variation of stacking sequences constituted by the A, B, and C and the A', B', and C' types of atomic arrays [22–26]. These 6 types, possessing variable four-layered structural units with the intervening layers of solute atoms along the thickness direction [22–26], were first proposed by Komura [22]. In terms of the stacking sequences, the C14 structure has AB' stacking; the C15, ABC stacking; and the C36, AB'A'C stacking. The atomic configurations of these three structures are suggested to be the Kagome net, based on the triangle, rhombohedral and hexagonal polytypes [20–24,27,28]. It is presumable that the changes in those 6 stacking sequences would be associated with the formation of different atomic configurations of  $\eta$  in the Al-

Zn-Mg-Cu aluminium alloys. The details are worth further investigation.

On the other hand, the group-theoretical point of view [29–33] has been employed to propose the characterization of the precipitate morphology and the determination of the number of precipitate variants with respect to the matrix. Initially, Buerger and Graef et al. [29,30] visualized the crystals as occurring in shapes that follow the symmetry of the crystallographic 32 point-groups under the matrix-free circumstance. Considering the solid state transformation, Kalonji and Cahn [31] and Boudeulle [32] illustrated that the precipitates forming from the matrix should be associated with the superimposed symmetry elements. The common point group between the matrix and the precipitate is also called the intersection point group [29–33]. From this resulting point-group, it can be extrapolated that the rotation or shifting of crystal interfaces will occur when precipitates grow from the matrix [31]. Moreover, the order of the intersection point group can be employed to deduce the number of equivalently-distributed variants of precipitates, i.e., the ratio of the order of matrix point group to that of the intersection point group [31–33]. Some investigations of steel alloys [34], magnesium alloys [35], and aluminium alloys [1,36] have provided examples to illustrate the morphologies of the precipitates and the number of variants equivalently distributed in the matrix.

Much attention has been paid to the observation of the plate-like morphology of  $\eta_2$  in the Al-Zn-Mg-Cu aluminium alloys, because of its orientation relationship, which is almost identical to that of  $\eta'$  due to the in-situ transformation of  $\eta' \rightarrow \eta_2$  [7], as shown in Table 1. As just mentioned, it is an intriguing subject for the application of point-group symmetries to the morphologies of crystals grown from crystalline matrixes. Here, in the present work a case study for the precipitates  $\eta'$  (or  $\eta_2$ ) in the aluminium matrix is demonstrated. The developed morphology and the number of equivalently-distributed variants of  $\eta'$  (or  $\eta_2$ ) are analysed by the intersection point-group between  $\eta'$  (or  $\eta_2$ ) and the Al matrix. The analysis procedure can be illustrated as follows. The  $\eta'$  (or  $\eta_2$ ) has the  $P6_3/mmc$  space group, which belongs to the  $6/mmm$  point group. Given that the point group of the Al matrix is  $m\bar{3}m$  with an order of 48, the symmetry elements of the intersection point-group

can be deduced from the orientation relationship between  $\eta'$  (or  $\eta_2$ ) and the Al matrix. The resulting intersection point-group is determined to be the  $\bar{3}m$  point group, with an order of 12. The number of variants can be determined to be the ratio of the order of the matrix point group to that of the intersection point group [31–33]. Therefore, 4 equivalently-distributed variants ( $48/12 = 4$ ) of  $\eta'$  (or  $\eta_2$ ) precipitates can form in the Al matrix. The morphology of  $\eta'$  (or  $\eta_2$ ) based on the resulting intersection point-group of  $\bar{3}m$  is suggested to be a di-hexahedron shape [29,30] at the nucleation stage. During the growth of an  $\eta'$  (or  $\eta_2$ ) precipitate, the lattice mismatches of the interfaces between precipitate and matrix should be taken into account. It is appropriate to conclude that the resulting plate-like morphology of  $\eta'$  (or  $\eta_2$ ) would be associated with the growth along the preferential directions with a low-strain energy on the hexagonal plane of this embryo of di-hexahedron crystal, so that the low strain-energy of the interface can be maintained [7]. It should be noted that although a number of investigations [1,35,36,38–40] have employed the above crystallographic method to determine the morphologies of precipitates [29,30], few of those works have connected them with the variable compositions of alloys, which lead to changes in lattice parameters to some extent (i.e., the lattice misfit). Therefore, the lower lattice misfit, dominating the lower interfacial energy during the growth of precipitates, should be considered a significant factor in the selected growth direction, for it leads to a different morphology [41,42]. The related viewpoint can be seen in previous investigations illuminating the growth morphology of precipitates [7,34,43,44]. By considering the lattice-mismatch factor, it can be found that the morphology of  $\eta'$  (or  $\eta_2$ ) will eventually develop into the plate-like shape. For other types of  $\eta$ , their equivalent variants and morphologies are listed in Supplementary Table 1 in Supplementary Material I.

In low magnification TEM images, the plate-like or rod-like  $\eta$  precipitates are easily found in the Al matrix along the zone axes of  $[001]_{Al}$ ,  $[110]_{Al}$ , and  $[1\bar{1}2]_{Al}$  [2,3,7,8,11,12,18,19,49]. It has been reported [2,12,49] that along the  $[001]_{Al}$  zone axis, a high number density of precipitates with the edge-on configurations of the  $\{001\}_{Al}$  planes is recognized as the plate-like  $\eta_1$ -type precipitate. The orientation relationship of  $\eta_1$  with respect to the Al matrix,

<sup>a</sup> The notations from  $\eta_1$  to  $\eta_{11}$  are used by Degischer et al. [12]. The morphologies of  $\eta_1$  to  $\eta_9$ , and  $\eta_{11}$  have been observed along the  $\langle 110 \rangle_{Al}$  zone axes. The morphology of  $\eta_{10}$  has not been identified by TEM, and the similar data were tabulated by Bendo et al. [11] and Chung et al. [7].

<sup>b</sup> The orientation relationship and morphology of  $\eta'$  is listed for reference.

<sup>c</sup> The novel  $\eta_4'$  and  $\eta_{12}$ -type precipitates were first analyzed in this present work.

<sup>d</sup> The morphologies of  $\eta_1$  and  $\eta_9$  have been confirmed in this present work.

(10 $\bar{1}0$ ) $\eta_1$ //(001) $_{Al}$  and [1 $\bar{2}10$ ] $\eta_1$ //[110] $_{Al}$ , can be analysed from the diffraction pattern [46,47]. Recently, Bendo et al. [11] have reported that HAADF STEM observation along the [110] $_{Al}$  zone axis apparently reveals the edge-on configuration of  $\eta_1$  with an atomic zig-zag stacking structure in hexagonal MgZn $_2$ , which was observed similarly in  $\eta_2$  along the [1 $\bar{1}2$ ] $_{Al}$  zone axis [3,18,19]. The zig-zag stacking structure possesses R units (the rhombohedral Zn-column units) and R $^{-1}$  units (the relatively 180°-rotated rhombohedral Zn-column units). Particularly, in  $\eta_1$ , the structure consists of R/R $^{-1}$  stacking order structures separated by the internal boundary, which is composed of flattened hexagonal stackings [11]. In works conducted by Singh et al. [50–53], Rosalie et al. [54,55], and Yang et al. [56] the flattened hexagonal arrays, which are adjacent to the rhombohedral atomic arrays of  $\eta_1$ , have frequently been observed, similar to those of Mg $_4$ Zn $_7$  in the Mg-Zn(-Y) magnesium alloys. A previous work [52] provided comprehensive views of the transition structures in between Mg $_4$ Zn $_7$ -MgZn $_2$ , and the atomic arrays of these two phases can thereby be distinguished. The flattened hexagonal unit in the Mg $_4$ Zn $_7$  phase is regarded as an intrinsic defect, the zone of the deficient Zn solute atoms. For the perfect MgZn $_2$  phase, the stoichiometry does not allow this type of defect. In order to recognize the differences in the atomic structures of MgZn $_2$  and Mg $_4$ Zn $_7$ , it is vital to identify their corresponding unit cells. The unit cell of MgZn $_2$  contains two differently-oriented pairs of rhombohedral arrays, as shown in Supplementary Fig. 1a (Supplementary Material II). On the other hand, the unit cell of Mg $_4$ Zn $_7$  contains six differently-oriented pairs of rhombohedral arrays, enveloped by two differently-oriented pairs of a flattened hexagonal array interweaved with a rhombohedral array, as shown in Supplementary Fig. 1b (Supplementary Material II) [52]. Whether the Mg $_4$ Zn $_7$  phase occurs during the growth of  $\eta_1$  in the Al-Zn-Mg-Cu aluminium alloys was not elucidated in the previous work [11].

It is known that the similar edge-on (001) $_{Al}$  configurations of  $\eta_1$  and  $\eta_9$ , based on their orientation relationships (i.e., (10 $\bar{1}0$ ) $\eta_1$ //(001) $_{Al}$  and [1 $\bar{2}10$ ] $\eta_1$ //[110] $_{Al}$  for  $\eta_1$ , and (1 $\bar{1}20$ ) $\eta_9$ //(001) $_{Al}$  and [1 $\bar{1}00$ ] $\eta_9$ //[110] $_{Al}$  for  $\eta_9$ ) would be hard to distinguish in low magnification TEM images along the [110] $_{Al}$  zone axis [7,11]. The relative rotation about 30° along [0001] $\eta_1$  leads to [1 $\bar{1}20$ ] $\eta_9$ //[001] $_{Al}$  [11], as portrayed in Fig. 1a, and results in different atomic arrangements on the projected facet of the (110) $_{Al}$  plane. However, owing to the very small number density of  $\eta_9$ , whether the atomic-scale structure of  $\eta_9$  is really the same as that of  $\eta_1$  has hardly been discussed in previous investigations [7,11,12,16,45,48]. This probing question of the atomic arrays of  $\eta_1$  and  $\eta_9$  will be reported in the present work.

In previous investigations [7,18,19,57],  $\eta_2$  phases were observed in high-resolution (HR)-TEM images along the [110] $_{Al}$  zone axis [7,57], and in high-resolution (HR)-STEM images along the [1 $\bar{1}2$ ] $_{Al}$  zone axis [18,19]. It was revealed that the  $\eta_2$  with the edge-on configuration on the (1 $\bar{1}1$ ) $_{Al}$  plane has (0001) $\eta_2$  spacing approximately equal to 4 times the (1 $\bar{1}1$ ) $_{Al}$  spacing (i.e.,  $d(0001)\eta_2$  (~0.860 nm)  $\cong$   $4d(1\bar{1}1)_{Al}$  (~4  $\times$  0.233 = 0.932 nm) [57]. The HR-STEM investigations characterized that the  $\eta_2$  phases have two kinds of intrinsic-stacking orders depending on the arrangements of the atomic columns. One is orthorhombic-like units connecting with rhombohedral-like units (O/R), named Type 1 order, and the other, rhombohedral-like units connecting with rhombohedral-like units (R/R) or the relatively rotated 180° rhombohedral-like units (R/R $^{-1}$ ), named Type 2 order [18,19]. It was suggested from the first principles calculation (using the Vienna ab initio simulation package, VASP) that the stable  $\eta_2$  phases possess the Type 2 order owing to their better coherency with respect to the Al matrix and the lower formation enthalpy than those of the Type 1 order [18].

According to previous works [7,12], the  $\eta_3$  type is presumed to differ in orientation from  $\eta_2$  with respect to the Al matrix, where

the orientation of  $\eta_3$  is obtained by rotating  $\eta_2$  about 30° along [0001] $\eta_2$ , leading to [1 $\bar{1}20$ ] $\eta_3$ //[110] $_{Al}$  (i.e., (0001) $\eta_3$ //(1 $\bar{1}1$ ) $_{Al}$  and [1 $\bar{1}20$ ] $\eta_3$ //[110] $_{Al}$ ), as shown in Fig. 1b. Fig. 1c indicates that the differences of the orientation relationships of  $\eta_5$ ,  $\eta_6$ , and  $\eta_7$  with respect to  $\eta_4$  are the relative rotations of ~11°, ~15°, and ~25° along the [0001] $\eta_4$  direction, respectively. Their atomic-scale structures have yet to be investigated. In addition, Table 1 also indicates the difference between  $\eta_4$  and  $\eta_{11}$  possessing the relative rotation of 30° along the [110] $_{Al}$  direction, leading to [10 $\bar{1}0$ ] $\eta_{11}$ //[1 $\bar{1}20$ ] $\eta_4$ //[110] $_{Al}$ .

On the basis of the orientation relationship and morphology of  $\eta_8$  types [2,7,11,12,16], the rod-like hexagonal configuration is schematically shown in Fig. 1d. In addition, it has been suggested [7] that the  $\eta_8$  phases serve as the nucleation sites of T phases formed at higher ageing temperature, for  $\eta_8$  types and T phases possess nearly the same orientation relationships with respect to the aluminium matrix. In Figs. 1b and d, the supposed morphologies of the  $\eta_{10}$  and  $\eta_{11}$  types are also indicated based on their orientation relationships, as reported in previous references [12,16,45].

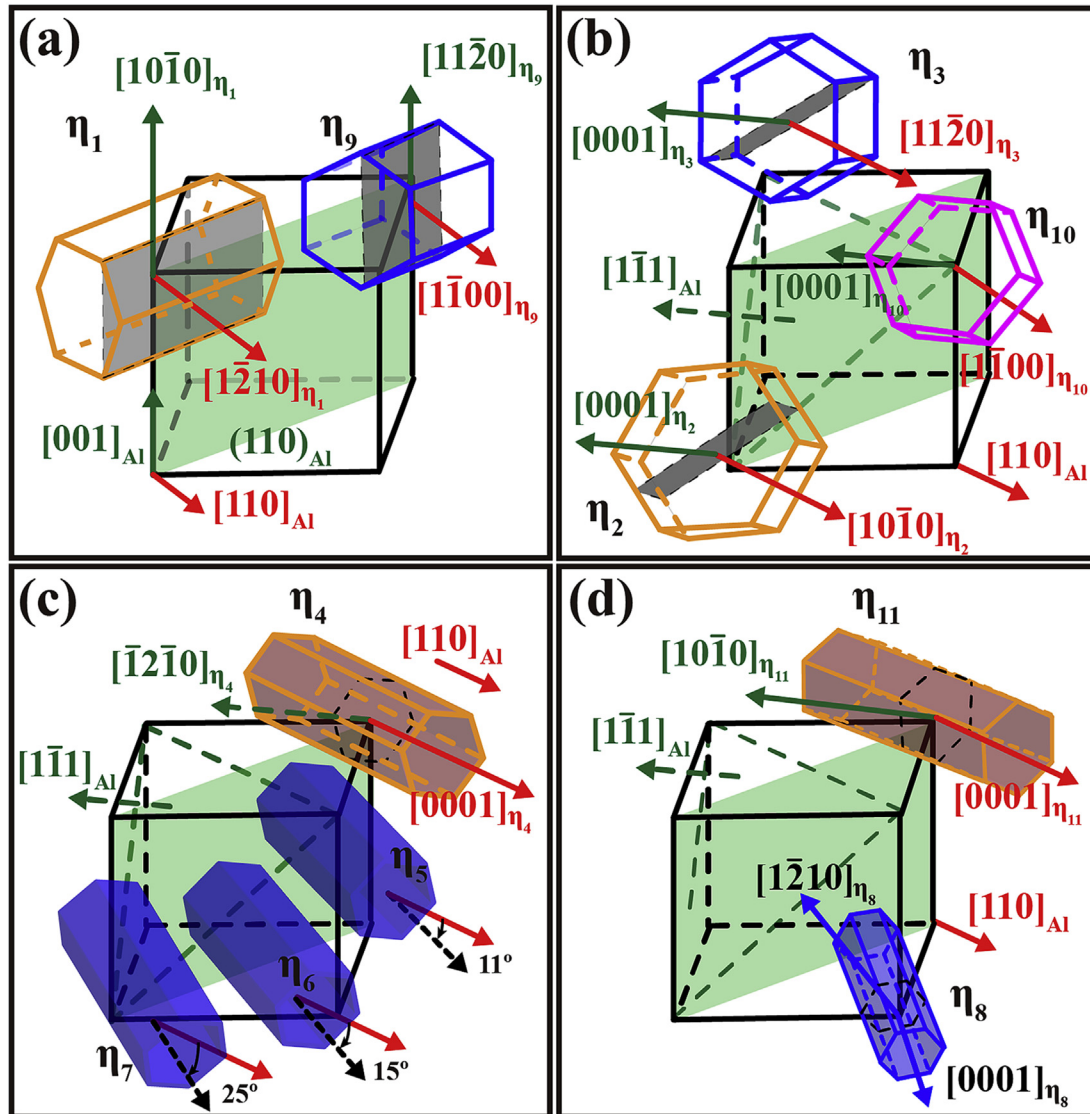

In the present paper, we describe the investigation of the atomic scale structures of  $\eta$  precipitates in ageing-treated AA7050 aluminium alloy by HAADF STEM. The atomic configurations, stacking faults or defects, orientation relationships with the Al matrix, morphologies, and growth mechanisms of the  $\eta$ -MgZn $_2$  crystal were elucidated from atomic images along the zone axes of [10 $\bar{1}0$ ] $\eta$ , [1 $\bar{2}10$ ] $\eta$  and [0001] $\eta$  taken mainly using  $\eta_2$ -type precipitates, and from comparison of the shapes and atomic arrays of various  $\eta$ -type precipitates grown with different orientations. According to the differences in orientation relationships with respect to the Al matrix, two novel types of  $\eta$ -precipitates have been proposed and named  $\eta_4'$  and  $\eta_{12}$ .

## 2. Materials and methods

An AA7050 aluminium alloy (Al-6.25Zn-2.14Mg-2.23Cu-0.05Fe-0.03Si, wt.%) was used in this study. After solution treatment (at 475 °C for 1 h with water quenching), the samples were immediately treated with a three-step ageing treatment: ageing at 120 °C for 8 h, at 165 °C for 1 h, and at 174 °C for 8 h with an applied constant tensile stress of 162.5 MPa (hereafter referred to as creep-age forming samples, CAF samples) [58]. The pre-observed TEM specimens were prepared by cutting discs from the selected samples along their loading direction and thinned to 0.07 mm thickness before they were twin-jet electropolished in a mixture of 33% nitric acid and 67% methanol at – 20 °C with a working voltage of 10 V. Then, the oxidation layers and the sample thickness were assumedly reduced by an M1040 NanoMill TEM specimen preparation system (E.A. Fischione Instrument), and the hydrocarbon contamination was subsequently removed by an M1070 Nanoclean plasma cleaner (E.A. Fischione Instrument). Afterwards, the TEM specimens were observed with an FEI Titan Chemi-STEM equipped with a spherical aberration corrector (Cs-corrector), which achieves a ~0.1 nm probe size with a beam current of ~70 pA and a convergence semi-angle of ~19.8 mrad. HAADF STEM images were recorded with a collecting angle range of 7.9–42.8 mrad of a HAADF detector. It is guaranteed that artefacts in the images are not caused by this electron probe [59,60]. The structure models for various atomic configurations of  $\eta$  precipitates were constructed with VASP [61,62] using the structure data proposed by Marioara [18] and Wolverton et al. [63].

## 3. Results and discussion

Chung et al. [7], who investigated the precipitate sequence of GP

**Fig. 1.** The schematic diagram indicating the morphologies of different types of  $\eta$  precipitates and their orientation relationships with respect to the Al crystal. (a)  $\eta_1$  and  $\eta_9$ ; (b)  $\eta_2$ ,  $\eta_3$ , and  $\eta_{10}$ ; (c)  $\eta_4$  and  $\eta_5$ – $\eta_7$ ; (d)  $\eta_8$  and  $\eta_{11}$ .

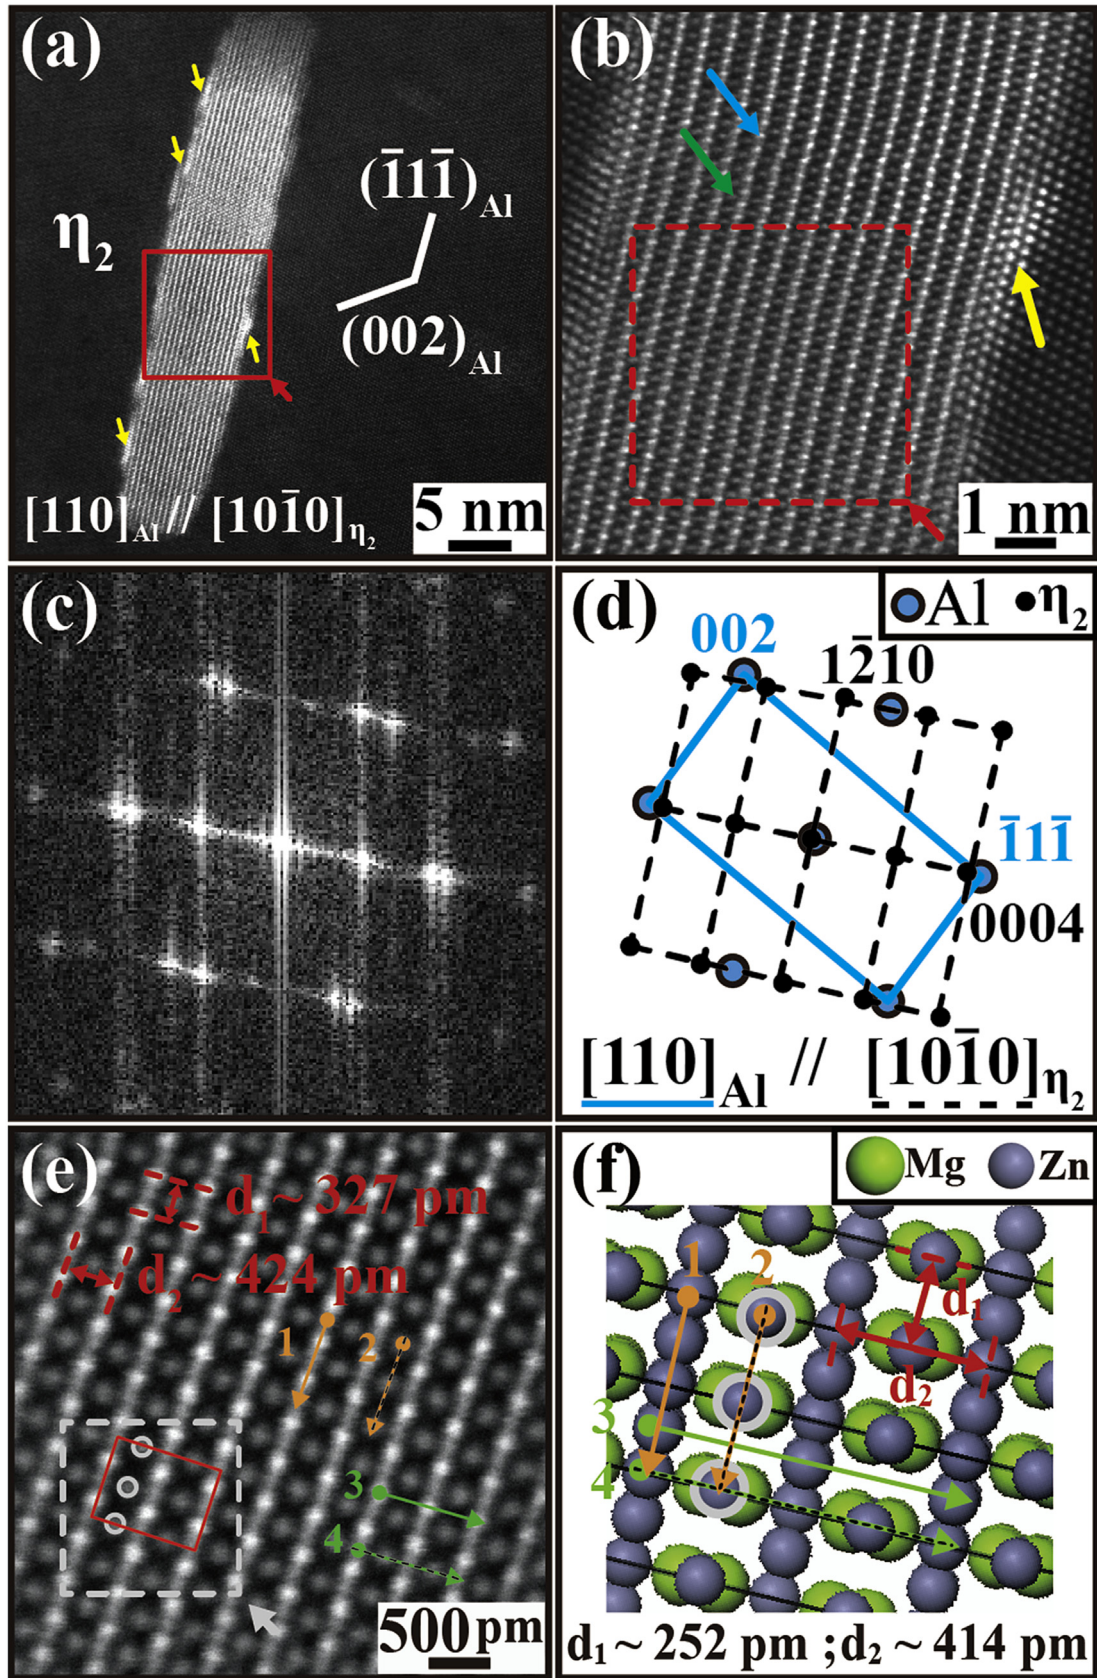

zones  $\rightarrow \eta'$  precipitates  $\rightarrow \eta$  precipitates in the AA7050 aluminium alloy by TEM, reported that stable  $\eta_2$  precipitates of larger size possess higher stability to prevent atomic-displacement or knock-on displacement caused by the electron beam during the observation, as compared to GP zones and  $\eta'$  precipitates. This provides a good opportunity to analyse the atomic structure of  $\eta$  precipitates by electron microscopy.

Fig. 2a shows an HR-HAADF STEM image of a precipitate, which was observed in the CAF film along the  $[110]_{\text{Al}}$  zone axis. Fig. 2b shows an enlarged image of the area indicated by the frame in Fig. 2a. Fig. 2c shows the fast Fourier transform (FFT) diffractogram from the area in Fig. 2b and Fig. 2d is the simulated electron diffraction (ED) patterns for analysing Fig. 2c. From its orientation relation with respect to the Al matrix indicated in Fig. 2d and Table 1, the precipitate can be regarded as the  $\eta_2$  type, which exhibits the edge-on configuration where the  $\eta_2$  phase grew on the  $(0001)\eta_2/(\bar{1}\bar{1}\bar{1})_{\text{Al}}$  habit plane.

Generally, atomic-scale HAADF STEM images are formed by incoherent imaging with electrons elastically scattered by atoms [64,65]. Only the transverse composition of the relative displacement between the atoms in the atomic column illuminated by an

electron beam is effective for HAADF STEM. The images are mainly formed by thermal-diffuse-scattering electrons and provide the atomic number (Z) contrast, approximately proportional to the squares of the atomic numbers of  $^{12}\text{Mg}$ ,  $^{13}\text{Al}$ ,  $^{29}\text{Cu}$  or  $^{30}\text{Zn}$  (the superscript is the Z) [66,67]. The intensity contrast is also proportional to the thickness of a material if the material is composed of the same elements. It should be noted that statistical displacements, such as differences in the position and size of atoms in alloys and the lattice distortion in deformed crystals, can cause electron diffuse scattering and contribute to HAADF STEM images. Furthermore, these displacements also influence the electron wave field in the crystal and thus HAADF STEM images [68]. The image in Fig. 2b closely resembles the simulated image for the structure of  $\text{MgZn}_2$  [69] reported by Li et al. [70]. Therefore, it is appropriate to claim that Fig. 2b shows a Z-contrast image of the  $\eta_2$ - $\text{MgZn}_2$  precipitate exhibiting the regular variation of stacking layers, which we call sandwiched stacking structures. Thus, it can be proposed from the nominal composition of  $\eta_2$  ( $\text{MgZn}_2$ ) that the higher contrast layer (indicated by the blue arrowhead) is an array of columns mainly composed of Zn atoms and that the lower contrast layer (indicated by the green arrowhead) includes Mg-columns.

**Fig. 2.** An  $\eta_2$  precipitate in ageing treated (CAF) AA7050 Al alloy. (a) A HAADF STEM image taken along the  $[110]_{\text{Al}} // [10\bar{1}0]_{\eta_2}$  zone axis showing the edge-on configuration of  $\eta_2$  on the  $(\bar{1}1\bar{1})_{\text{Al}}$  plane. (b) An enlarged image of the area indicated by the frame in (a). (c) The FFT diffractogram from the area of (b). (d) The simulation ED pattern. (e) An enlarged image of the area indicated by the red frame in (b). (f) The atomic structure of  $\eta_2$ -MgZn<sub>2</sub>, pointing out the atomic configuration of the white dashed frame (e). (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

Apparently, the HAADF STEM image in Fig. 2b is correlated to the chemical composition of the  $\eta_2$ -MgZn<sub>2</sub> phase and the Al matrix. The atomic column intensity along the  $[110]_{\text{Al}}$  direction in the Al matrix was measured on eleven  $(\bar{1}11)$  lattice fringes, indicated by Lines 1–11 in Supplementary Fig. 2a (Supplementary Material II). Supplementary Fig. 2b (Supplementary Material II) illustrates the intensity line profile along Line 1. Supplementary Fig. 2c (Supplementary Material II) shows the intensities of 100 atomic columns on Lines 1–11. The average intensity was estimated to be  $1400 \pm 106$  counts. The error (standard deviation) of 106 counts is higher than an assumed statistical variability of 37 ( $\sim \sqrt{1400}$ ) counts in the case of detecting a constant beam (with an averaged intensity of 1400 counts). It is presumed that the larger intensity fluctuation among atomic columns is caused by vacancies of Al atoms or small amounts of soluted atoms, such as Mg, Zn or Cu remaining in the Al matrix, indicating Z contrast, since the thickness can be regarded to be uniform over such a small region.

Fig. 2e shows the enlarged image of the area indicated by the red frame in Fig. 2b. Fig. 2f indicates the calculated structure of  $\eta_2$ , which was drawn using the lattice parameters of  $\eta_2$  obtained by VASP [63] and corresponds to the image of the area indicated by the white dashed frame in Fig. 2e. To understand the correlation between the real and calculated structures of  $\eta_2$ , the foci were specifically placed on the spacings between atomic layers and the intensity line profiles along different lattice fringes. Using the Al matrix lattice fringes (assuming  $d(002)_{\text{Al}} = 0.202$  nm) for calibration as indicated in Figs. 2c and d, the distances between atomic columns parallel and vertical to the  $[\bar{1}11]_{\text{Al}}$  direction,  $d_1$  and  $d_2$ , are referred to as  $1/2 d(1\bar{2}10)_{\eta_2}$  and  $1/2 d(0001)_{\eta_2}$ .  $d_1 \sim 327$  pm and  $d_2 \sim 424$  pm, as shown in Fig. 2e. The calculated distances are  $d_{1(\text{VASP})} \sim 252$  pm and  $d_{2(\text{VASP})} \sim 414$  pm, as indicated in Fig. 2f. Hence, the lattice constants of the present  $\eta_2$  crystal are  $a \sim 0.654$  nm and  $c \sim 0.848$  nm, while theoretical and experimental lattice constants of MgZn<sub>2</sub> have been reported as  $a = 0.504$  nm and  $c = 0.828$  nm by VASP calculation [63], and  $a = 0.522$  nm and  $c = 0.857$  nm by X-ray diffraction [69], respectively. In any case, the incompatible result of the lattice constants might be caused by the dynamic  $\eta_2$ -precipitate chemistry changes and the vacancy-atom interactions during the ageing treatment, as suggested by Ringer and Hono [1]. It can be seen as the fluctuation of the intensity among equivalent atomic columns (along Lines 1, 2, 3, and 4 indicated in Figs. 2e and f) in the HAADF STEM image, as indicated in Supplementary Fig. 3 (Supplementary Material II). These figures present the intensity line profiles along the lattice fringes indicated by Lines 1 and 2 in Figs. 2e and f. Line 1 is a  $[10\bar{1}0]$  projection of atoms on the plane at  $z = 1/4$  in the space group  $P6_3/\text{mmc}$ , where the atoms occupy three positions of Wyckoff notation (6h). Taking into account the structure of MgZn<sub>2</sub> [69], Supplementary Fig. 3a (Supplementary Material II) shows that Line 1 may be regarded as an array of  $\cdots \text{Zn}, 2\text{Zn}, \text{Zn}, 2\text{Zn}, \cdots$  in a thickness of 2 unit cells or a double  $(10\bar{1}0)$  plane. Similarly, Line 2, which is a projection of atoms at  $z = 0$ , is an array of  $\cdots \text{Zn}, \text{Zn}, \cdots$ , which occupies positions at one position of Wyckoff notation (2a). Supplementary Fig. 3b (Supplementary Material II) shows the intensity line profiles along the lattice fringes indicated by Lines 3 and 4 in Figs. 2e and f. Line 3 is a  $[10\bar{1}0]$  projection of atoms on one  $(1\bar{2}10)$  plane and must be an array of  $\cdots 2\text{Zn}, 2\text{Zn}, 2\text{Zn}, \cdots$ . Line 4 is a  $[10\bar{1}0]$  projection of atoms on another  $(1\bar{2}10)$  plane and must be an array of  $\cdots \text{Zn}, \text{Mg}, \text{Zn}, \text{Mg}, \text{Zn}, \text{Mg}, \text{Zn}, \text{Mg}, \cdots$ . A general survey of these intensity line profiles exhibits the Z contrast of MgZn<sub>2</sub> crystal. The intensity among equivalent atomic columns on Line 1 (and also Lines 2, 3, and 4), however, does not seem the same within statistical variability. The fluctuation of intensity exceeding the statistical variability may be ascribed to the difference in chemical composition among the atomic columns, which is caused by substitution of

$^{13}\text{Al}$ ,  $^{29}\text{Cu}$ ,  $^{26}\text{Fe}$ , or  $^{14}\text{Si}$  atoms or vacancies for Zn sites (and also Mg sites on Line 4).

An area near the  $\eta_2/\text{Al}$  interfaces, indicated by a solid yellow arrow in Fig. 2b, exhibits abnormally strong bright contrast. Presumably, the lattice mismatch between the  $\eta_2$  and Al crystals would cause higher interfacial energy or higher lattice strain energy near the interface of  $\eta_2/\text{Al}$ , inducing the change of solute atom concentration, which is suggested to be a chemical effect or Suzuki effect for segregation to stacking faults [71]. Hence, the brighter contrast in the HAADF STEM image is ascribable to the segregated Zn and also Cu atoms in the Al lattices near the interface, as similarly reported in previous investigations [72–80] revealing the segregation of solute atoms nearby the precipitate/matrix interfaces in magnesium alloys [72–74] and aluminium alloys [75–80].

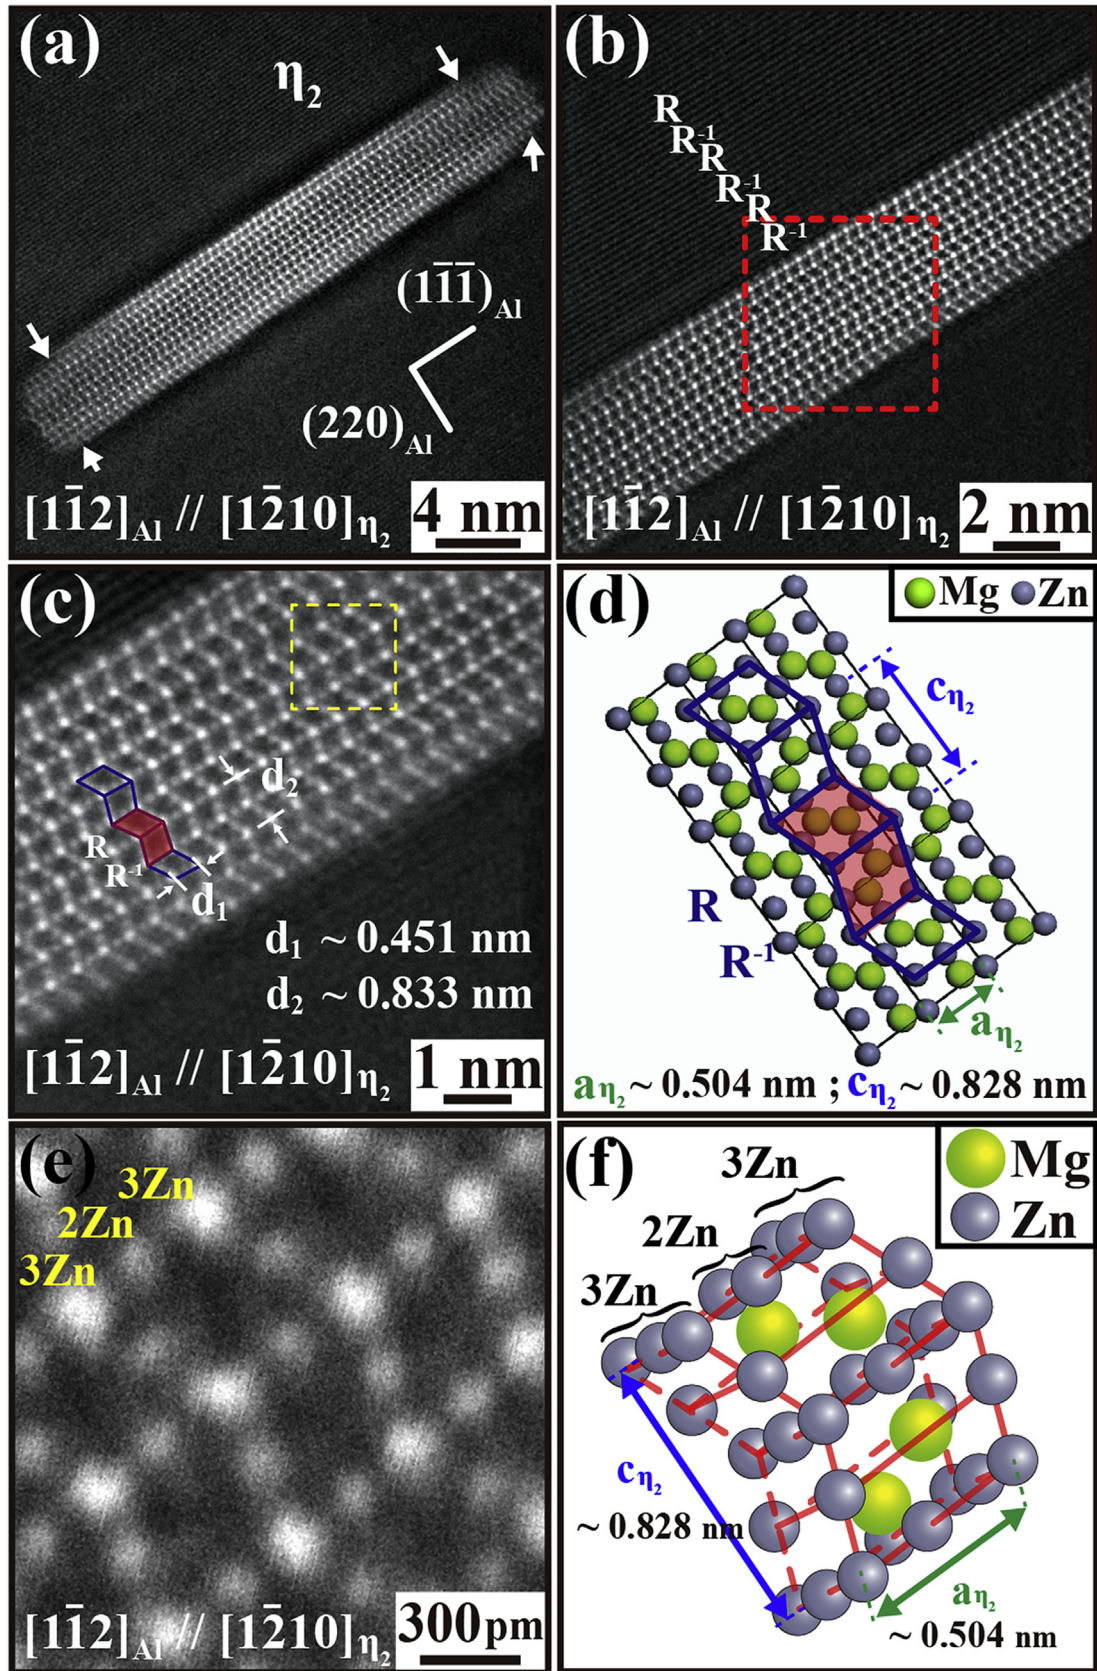

Bendo [11] and Marioara et al. [18] observed a similar  $R/R^{-1}$  stacking layer-structure, which contains the rhombohedral-like unit (R) connecting with another rhombohedral-like unit ( $R^{-1}$ ) rotated  $180^\circ$  relative to R, in HR-STEM images of  $\eta_1$  and  $\eta_2$  precipitates along the  $[110]_{\text{Al}}$  and  $[1\bar{1}2]_{\text{Al}}$  zone axes, respectively. These precipitates exhibit the edge-on configurations on the interfaces with the Al matrix parallel to the  $(1\bar{1}1)_{\text{Al}}$  plane and possess the stacking layers in the precipitates. The  $R/R^{-1}$  was presumed to be one kind of stacking structures that existed in all types of  $\eta$  [11]. We also observed  $\eta_2$  precipitates with the uniform  $R/R^{-1}$  stacking layers in HAADF-STEM images of the CAF sample along the  $[1\bar{1}2]_{\text{Al}}$  zone axis, as seen in Fig. 3.

The growth of  $\eta$  precipitates can be interpreted simply as follows. An  $\eta$  precipitate or MgZn<sub>2</sub> crystal grown via  $\eta'$  from GPII zones in the Al matrix [7] has a characteristic habit plane, indicated in Table 1. As mentioned above, a kind of chemical effect segregates solute atoms such as Zn, Cu, and Mg from the matrix and diffuses them into a region near the interface of the  $\eta/\text{Al}$  crystals, which is a habit surface of the MgZn<sub>2</sub> crystal. Once a crystal nucleus forms on the surface of the precipitated MgZn<sub>2</sub> crystal, it grows laterally on the surface, supplied by precursors of Zn and Mg from the nearby matrix, which is rich with solute atoms. The layer-by-layer growth occurs following the most stable stacking sequence of  $R R^{-1} R R^{-1} R R^{-1} \cdots$  as MgZn<sub>2</sub> crystal, consecutively. As is often the case with layer-by-layer growth, steps form along the edges of layers, as indicated by small white arrowheads in Fig. 3a. The crystal goes on growing laterally at the steps, supplied with precursors. This mechanism is common in the growth of single crystal thin films of semiconductor material by methods such as metal-organic chemical vapour deposition and atomic layer deposition [81].

Two spacings,  $d_1$  and  $d_2$ , indicated in Fig. 3c, were measured, and the results were  $d_1 \sim 0.451$  nm and  $d_2 \sim 0.833$  nm, which correspond to the lattice constants  $a$  and  $c$ , respectively. Both precipitates shown in Figs. 2 and 3 were in the same sample and of the same  $\eta_2$  type but had lattice constants different from each other and from the calculated ones shown in Fig. 3d. The chemical composition must differ slightly among precipitates even if they are of the same type of  $\eta$  grown in the same sample. Bendo et al. [11] reported an example of the disrupted-arrangement inside  $\eta_1$  where the  $R/R^{-1}$  stacking layers were separated by internal boundaries composed of irregular atomic arrangements, and they assumed that the precipitate was in the early stages of growth. The Z-contrasts can also be seen clearly in an enlarged image in Fig. 3e and are easily understandable from the structure schematically shown in Fig. 3f, where 3Zn, 2Zn, and 3Zn indicate Zn columns with 3, 2, and 3 atoms in the rhomb unit-cell, respectively. However, Mg-columns along the long diagonal line are blurred, possibly due to disturbance from the Al matrix beneath the precipitate and the weak Z-contrast intensity of Mg atoms.

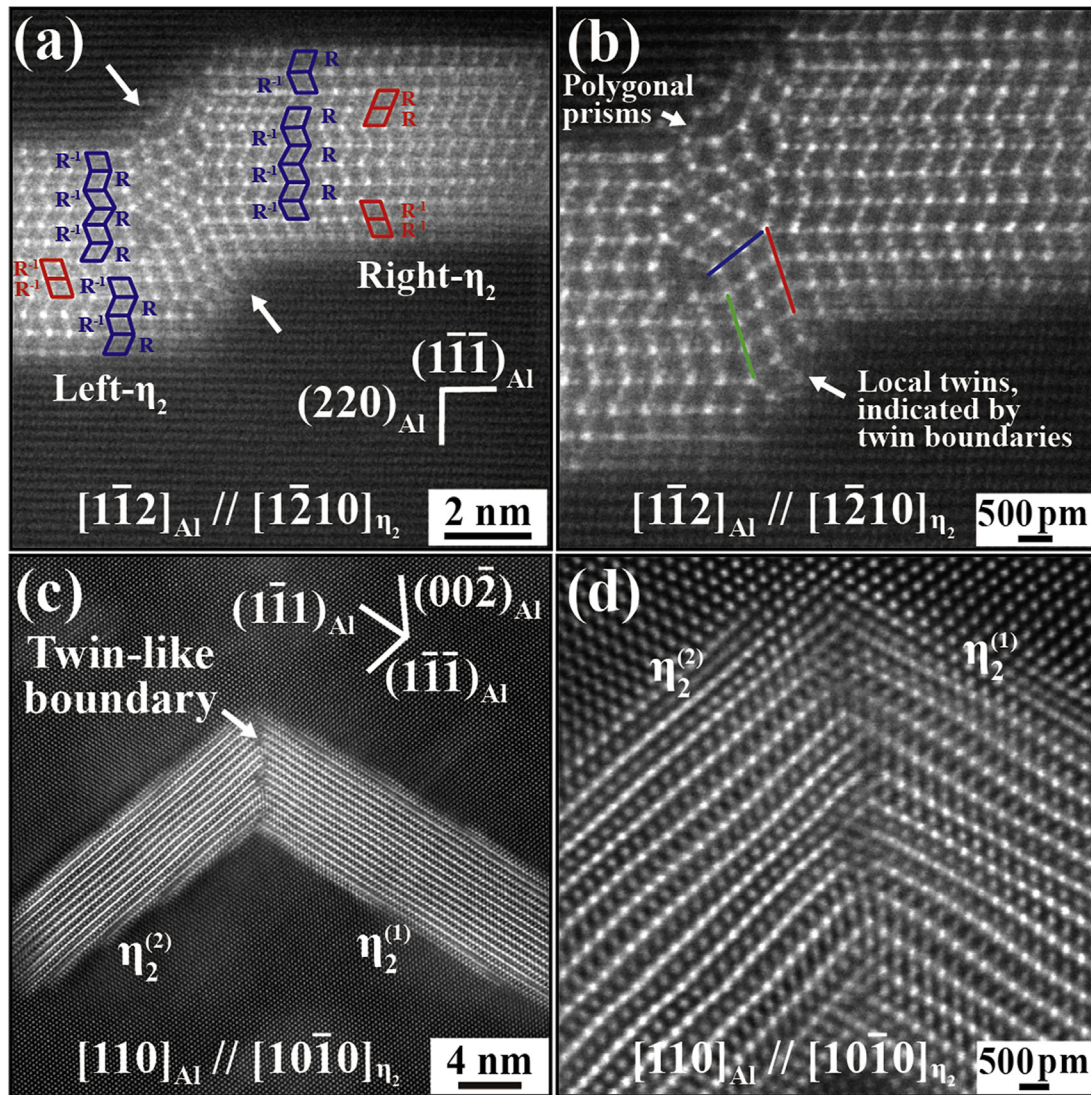

Figs. 4a and b show HAADF-STEM images of a different sort of  $\eta_2$

**Fig. 3.** Another  $\eta_2$  precipitate in the CAF Al alloy. (a) A HAADF STEM image taken along  $[1\bar{1}2]_{Al} // [1\bar{2}10]_{\eta_2}$  zone axis showing its edge-on configuration on the  $(1\bar{1}\bar{1})_{Al}$  plane. (b) An enlarged image of part of (a), exhibiting a sound ordering of  $R/R^{-1}$  in  $\eta_2$ . (c) The enlarged image of the area indicated by the frame in (b), indicating the measured lattice spacings,  $d_1$  and  $d_2$ . (d) The structure of  $MgZn_2$  projected along  $[1\bar{1}2]_{Al} // [1\bar{2}10]_{\eta_2}$ , indicating calculated parameters,  $a$  and  $c$ . (e) An enlarged HAADF STEM image of rhomb ( $RR^{-1}$ ) units. (f) A schema of a pair of  $RR^{-1}$  units, visualizing the atomic columns along the  $[1\bar{2}10]_{\eta_2}$  zone axis.

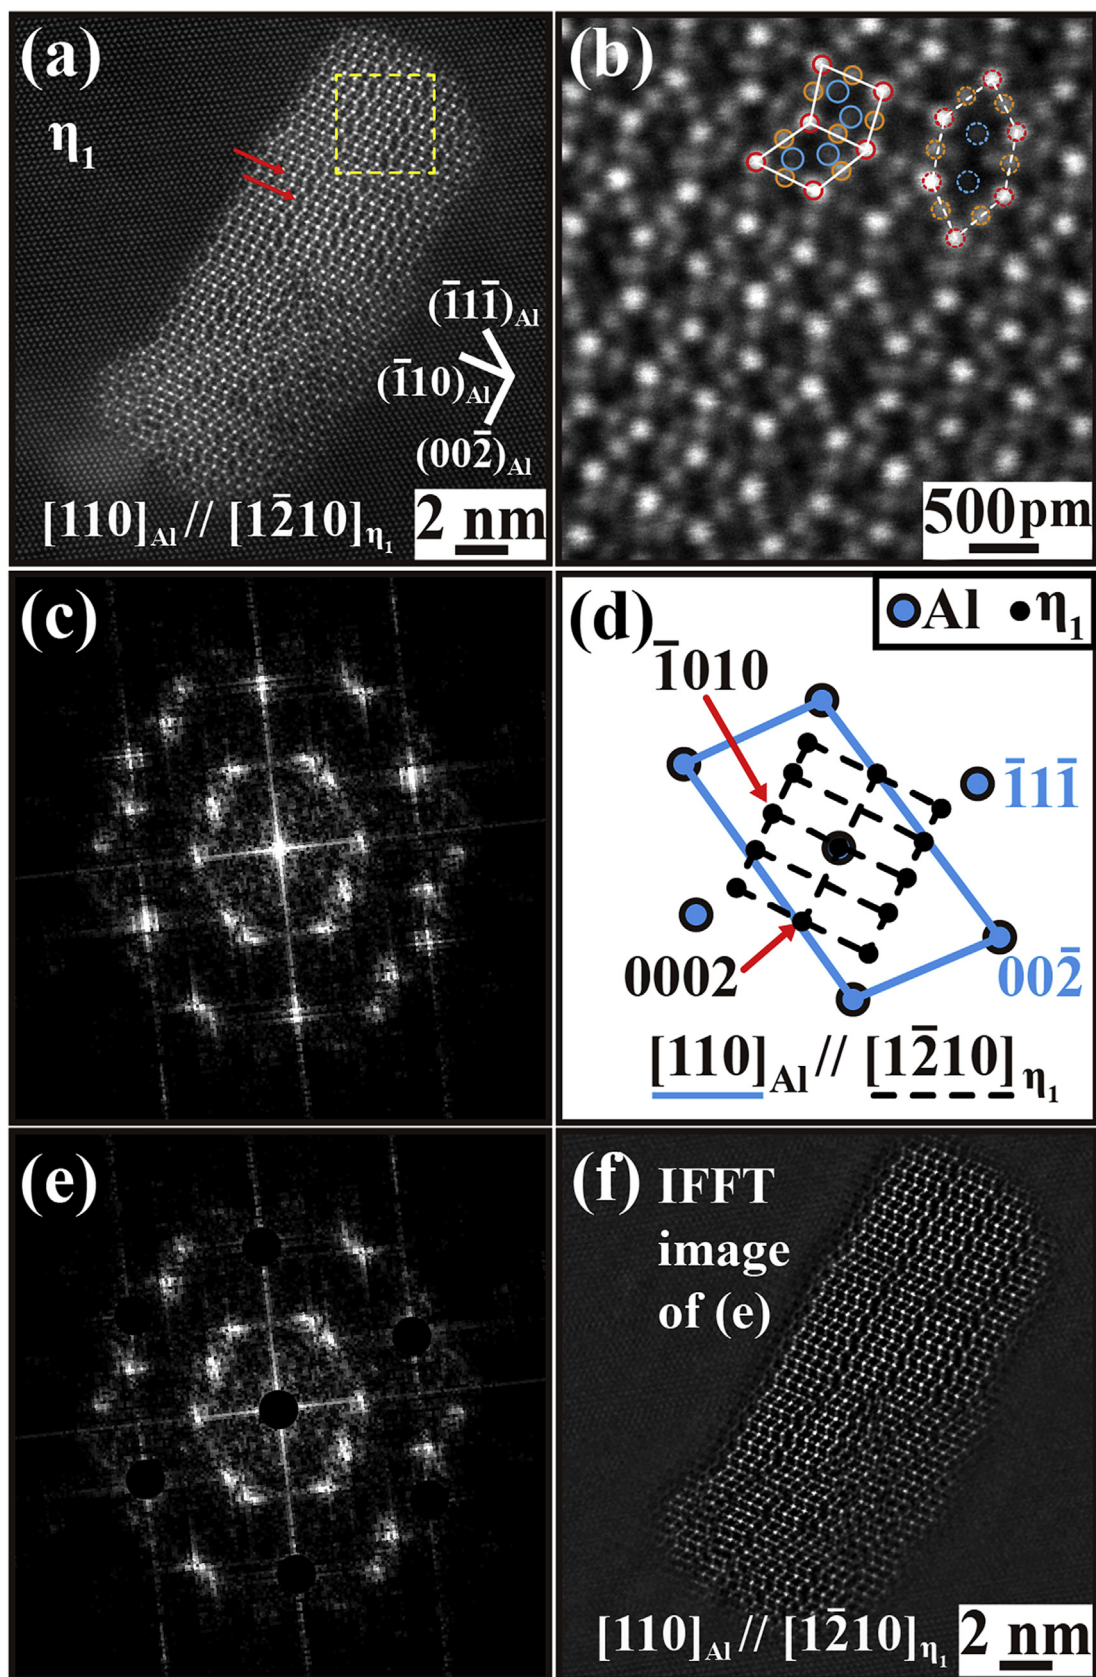

**Fig. 4.** Coalescence growth between  $\eta_2$  crystals precipitated in the CAF Al alloy. (a) HAADF STEM image taken along the  $[1\bar{1}2]_{\text{Al}} // [1\bar{2}10]_{\eta_2}$  zone axis. Two crystals, left- $\eta_2$  and right- $\eta_2$ , which precipitated on almost the same  $(1\bar{1}\bar{1})_{\text{Al}}$  planes, coalesced. They had an R/R $^{-1}$  stacking structure including stacking faults. (b) An enlarged image of the coalesced region in (a), revealing the complicated bonding boundary with local twinning and various defect structures. The twin boundaries are indicated by three coloured bars. (c) HAADF STEM image taken along the  $[110]_{\text{Al}} // [10\bar{1}0]_{\eta_2}$  zone axis. Two variants of  $\eta_2$  precipitates,  $\eta_2^{(1)}$  and  $\eta_2^{(2)}$ , which precipitated on different Al planes of  $(1\bar{1}\bar{1})_{\text{Al}}$  and  $(1\bar{1}\bar{1})_{\text{Al}}$ , respectively, coalesced and resulted in a twin-like structure. They exhibited a sandwiched structure. (d) An enlarged image of the coalesced region in (c), revealing the atomic arrays of the boundary.

precipitate grown on the  $(1\bar{1}\bar{1})_{\text{Al}}$  plane, which were also observed along the  $[1\bar{1}2]_{\text{Al}}$  zone axis in the Al matrix. The atomic configuration is composed of two parts: the left part, which comprises layers with  $\cdots R^{-1}R \cdots / R^{-1}R^{-1} / \cdots R^{-1}R \cdots$ , and the right part, which comprises layers with  $\cdots RR^{-1} \cdots / RR / \cdots RR^{-1} \cdots / R^{-1}R^{-1} / \cdots RR^{-1} \cdots$ , as marked by blue and red frames in Fig. 4a. Both the left and the right parts have stacking faults such as RR or R $^{-1}R^{-1}$  against the proper ordering of RR $^{-1}R^{-1}$ . The existence of these stacking faults is not abnormal but rather common in  $\eta$  precipitates. These crystals grew layer-by-layer, separately. Once an embryo nucleated in an irregular stacking manner, the layer with this order would extend laterally over the surface layer, even if the formation of the stacking fault was unfavourable in energetics, because the ordering was controlled only by the secondary layer beneath the surface in the stacking structures. These stacking faults were of neither the Shockley-type nor the Frank-type because partial dislocations were never observed; rather, they were simple stacking faults caused by mis-stacking of the layer during the growth. It may be regarded as a result of the lateral growth and collision of two  $\eta_2$  particles that

precipitated on almost the same  $(1\bar{1}\bar{1})_{\text{Al}}$  layers but with different stacking orders. Two particles encountered each other and then generated a complicated boundary (as indicated by arrows in Fig. 4a), which was composed of local twins and polygonal prisms, almost remaining atomic columns along  $[1\bar{2}10]_{\eta_2} // [1\bar{1}2]_{\text{Al}}$ , as seen in Fig. 4b. Furthermore, Figs. 4c and d show HAADF STEM images of two variants of  $\eta_2$ -crystals with the sandwiched stackings, observed along the  $[110]_{\text{Al}}$  zone axis. These two variants, indicated as  $\eta_2^{(1)}$  and  $\eta_2^{(2)}$ , developed on two different Al planes of the  $(1\bar{1}\bar{1})_{\text{Al}}$  and  $(1\bar{1}\bar{1})_{\text{Al}}$  planes, respectively. They coalesced with a twin relation and the twin-like boundary was nearly parallel to the  $(00\bar{2})_{\text{Al}}$  plane, as shown in Fig. 4d. Hence, we found that the specific boundaries which were formed by coalescence between two crystals precipitated on the same  $(1\bar{1}\bar{1})_{\text{Al}}$  layers (as shown in Fig. 4a) or on different  $\{1\bar{1}\bar{1}\}_{\text{Al}}$  layers (as shown in Fig. 4c).

Fig. 5a shows a HAADF-STEM image of a precipitate in the CAF Al alloy observed along the  $[110]_{\text{Al}}$  zone axis. Fig. 5b shows an enlarged image of the area indicated by the frame in Fig. 5a, disclosing the atomic arrangement in detail. Its FFT diffractogram

**Fig. 5.** An  $\eta_1$  precipitate in the CAF Al alloy. (a) A HAADF-STEM image taken along the  $[110]_{\text{Al}} // [1\bar{2}10]_{\eta_1}$  zone axis showing its edge-on configuration on the  $(00\bar{2})_{\text{Al}}$  plane. (b) An enlarged image of the area indicated by the yellow frame in (a), showing a couple of  $R/R^{-1}$  units in an  $RR^{-1}RR^{-1}$  stacking layer and one of the flattened hexagons that form a defect layer between the  $RR^{-1}RR^{-1}$  stacking layers. Red, orange, and blue circles indicate Zn, Zn/Mg, and Mg atomic columns, respectively. (c) FFT diffractogram from the whole area in (a). (d) Simulated ED pattern for the  $\eta_1$  precipitate with the Al matrix, revealing the orientation relationship of  $(10\bar{1}0)_{\eta_1} // (001)_{\text{Al}}$  and  $[1\bar{2}10]_{\eta_1} // [110]_{\text{Al}}$ . (e) The selected reflection spots only from  $\eta_1$ . (f) IFFT image reconstructed using (e), disclosing more clearly the structure of  $\eta_1$ , in particular irregular or flattened-hexagon layers and other defects in the  $RR^{-1}$  layers. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

shown in Fig. 5c confirmed this precipitate mainly to be an  $\eta_1$  crystal with the orientation relationship of  $(10\bar{1}0)_{\eta_1} // (001)_{Al}$  and  $[12\bar{1}0]_{\eta_1} // [110]_{Al}$ , considering the simulated ED patterns for  $\eta_1$  and Al crystal shown in Fig. 5d. The main part of the precipitate comprised R/R<sup>-1</sup> stacking layers. However, a layer composed of flattened hexagons, as projections of atomic columns, was observed between the regular R/R<sup>-1</sup> stacking layers, as seen in the frame in Fig. 5a. This structure has been reported and analysed by Bendo et al. [11]. It may be noted that this  $\eta_1$  precipitate grew laterally on the  $(001)_{Al}$  plane, exhibiting the  $(10\bar{1}0)_{\eta_1}$  habit plane, while the  $\eta_2$  precipitates grew laterally on the  $(1\bar{1}\bar{1})_{Al}$  plane, exhibiting the  $(0001)_{\eta_2}$  habit plane. In other words, in the  $\eta_1$  precipitate, layers of  $\cdots RR^{-1} RR^{-1} \cdots$  grew laterally on the  $(10\bar{1}0)_{\eta_1}$  surface, successively, while in the  $\eta_2$  precipitate, a layer of  $\cdots RR \cdots$  and a layer of  $\cdots R^{-1} R^{-1} \cdots$  grew laterally on the  $(0001)_{\eta_2}$  surface, alternately. The difference in growth between  $\eta_1$  and  $\eta_2$  precipitates may be ascribed to the difference in the initially-nucleated  $\eta_1$  and  $\eta_2$  layers on the  $(001)_{Al}$  and  $(1\bar{1}\bar{1})_{Al}$  planes, respectively, where Al planes are replaced by Zn/Mg atoms. As a result, the  $\eta_1$  precipitates became rods, while the  $\eta_2$  precipitates became plates, as shown in Table 1.

In Fig. 5a, the atomic arrays of  $(0002)_{\eta_1} // (\bar{1}10)_{Al}$  (as indicated by red arrows) do not pass through the fault layers composed of several flattened hexagonal arrays continuously connected with each other and neatly distributed on the  $(00\bar{2})_{Al}$  plane; rather, they are suddenly interrupted by a single rhombohedral array in the layer. The stronger Zn fringes in Z contrast change to weaker Zn fringes. This can be clearly seen in Fig. 5f, which is the inverse FFT image reconstructed using only diffraction spots from  $\eta_1$  (Fig. 5e) in the FFT diffractogram of the image in Fig. 5a. That is, the fringes of Zn atoms in Wyckoff position 6(h) changed to the fringes of Zn atoms in position 2(a) [69]. Therefore, the stacking fault layer can be regarded as a kind of antiphase boundary [11], which is clearly different from the typical structure of  $Mg_4Zn_7$  [51,52,54]. The growth of the layer with the antiphase against the substrate may occur by nucleation of a mismatched embryo, similar to the growth of an  $\eta_2$  crystal with stacking faults. However, another mechanism for the formation of the antiphase boundary can be proposed here. Two  $\eta_1$  particles, which are precipitated on the  $(00\bar{1})_{Al}$  planes with a short spacing, develop in layer-by-layer growth, encounter each other, and then coalesce into one particle. When the stacking order of the merged region is different from those of the regular R/R<sup>-1</sup> stackings, coalescence accompanied by an antiphase grain boundary will occur. In this case, the antiphase grain boundary has a complicated structure wherein the Zn, Cu and Mg atoms near their surfaces are rearranged, leading to the boundary layer being composed of flattened hexagons, as shown in Figs. 5a and b. Subsequently, the particle grows further and the grain boundary has a possibility to be curved. Thus, the precipitate in Fig. 5a can be regarded as the result of coalescence of several  $\eta_1$  particles. Fig. 5b shows an enlarged image of the area of the yellow frame in Fig. 5a, where an R/R<sup>-1</sup> rhombohedral unit and a flattened hexagonal unit are illustrated. Supposed positions of Zn and Mg columns in the flattened hexagonal unit are shown for comparison with the Zn and Mg columns in the R/R<sup>-1</sup> rhombohedral unit. As compared with Fig. 5a, the inverse FFT image in Fig. 5f reveals thinner layers in the Al matrix enclosing the  $\eta_1$  precipitate. This supports the lateral or layer-by-layer growth of the precipitate by rhomb-unit layers.

Highly complicated defect structures were found in Figs. 5a and b. Supplementary Fig. 4a (Supplementary Material II) displays irregular arrangements, such as a rhombic unit surrounded by several pairs of flattened hexagonal/rhombic units (Supplementary Fig. 4b in Supplementary Material II) and a random flattened hexagonal unit connecting with rhombic units (Supplementary Fig. 4c in Supplementary Material II), which are probably consistent with the varied atomic configurations caused by the effect of the

dislocation-assisted precipitate formation in the Zn-Mg alloy [56]. Furthermore, Fig. 5f discloses much more clearly the structure of  $\eta_1$ , comprising the areas constructed with the regular R/R<sup>-1</sup> layers, the fault layers of flattened-hexagons between them, and other defects. The origin of the complicated structures is unclear but may be assumed to result from the coalescence between precipitates formed on different  $\{001\}_{Al}$  habit planes.

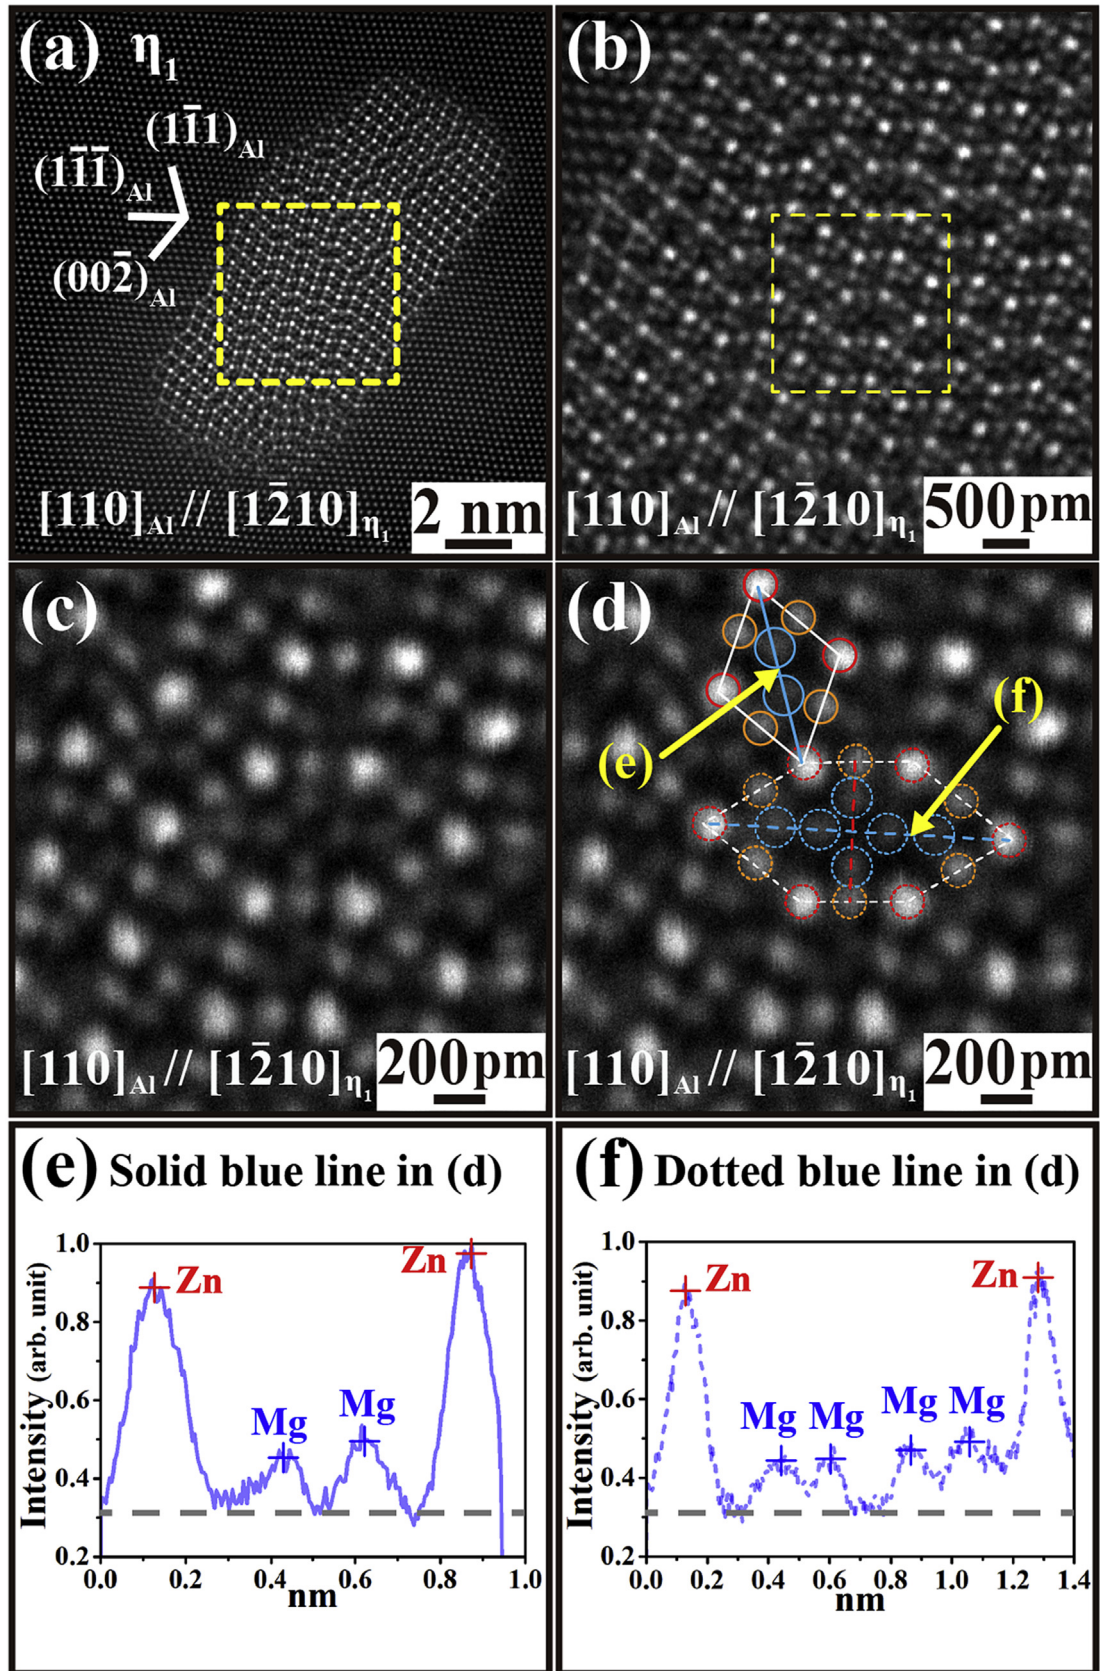

The HAADF-STEM image in Fig. 6a shows an  $\eta_1$  precipitate observed along the  $[110]_{Al}$  zone axis. This precipitate has a habit plane along the interface of the  $(00\bar{2})_{Al} // (10\bar{1}0)_{\eta_1}$  plane. Particularly, its configuration contains the flattened hexagonal units connected with one or two rhombohedral units distributed along different orientations (i.e., the flattened directions respectively lie on the different planes of  $(00\bar{2})_{Al}$  and  $(1\bar{1}\bar{1})_{Al}$ ). Although the differently-oriented flattened hexagonal units are similar to the atomic structure of planar defects within  $Mg_4Zn_7$  reported in previous investigations [52,54], the continuously-connected flattened hexagonal units are completely inconsistent with the typical structure of  $Mg_4Zn_7$  [51,52,54]. They were presumably caused by the introduced defects such as vacancies, dislocations, and stacking faults, or the coalescence of two variants of  $\eta_1$  during the growth of precipitates. Thus, this characteristic of  $\eta_1$  (Fig. 6a) should be further investigated by using the simulated atomic models in the further work. Fig. 6b shows an enlarged image of the area indicated by the frame in Fig. 6a. It explicitly reveals that the structures, composed of a rhombohedron and a flattened-hexagon unit, are similar to those in position b in Fig. 5a.

The atomic structure of the rhombohedron was elucidated by HR-STEM and first principle calculation [3,11,18,19], while the flattened hexagon unit was only observed in the projected atomic-scale micrographs, and its structures were assumed [3,11]. Fig. 6c shows the enlarged images of the areas indicated by the frames in Fig. 6b. The intensity profiles along Line (e) and Line (f) in Fig. 6d, which is the same image as Fig. 6c, are illustrated in Figs. 6e and f, respectively. By taking the Z contrast, the line profiles definitely placed the Mg atomic columns as well as the Zn and Zn/Mg atomic columns in both the rhombohedral unit and the flattened hexagonal unit. The positions of Mg, Zn, and Zn/Mg atomic columns are respectively indicated by blue, red, and orange circles in Fig. 6d.

The various morphologies of all the  $\eta$  types listed in Table 1 are presumably associated with the different growth rates of crystal facets. Regarding their orientation relationships with respect to the Al matrix, the edge-on configurations of plate-like, rod-like or prism-like  $\eta$  are difficult to distinguish with low magnification TEM/STEM. As previously reported [7,43], an effective strategy for extrapolating the morphologies of the hexagonal close-packed precipitates is based on the calculations of lattice misfits in three growth directions with respect to the  $(0001)$  basal plane (i.e., one is the lateral growth direction vertical to the basal plane, and the others belong to the layer-by-layer growth direction parallel to the basal plane). The coherency interfaces with the smaller lattice misfit would lower the energy barrier of the precipitate growth. Therefore, the inversely proportional relationship between the lattice misfit and the growth rate can also be employed to evaluate the morphologies of  $\eta_1$  precipitates.

The misfit vertical to the  $(0001)_{\eta_1}$  basal plane  $(\delta(v))_{(0001)}$  was relatively smaller:  $|d[0001]_{\eta_1} - 3d[1\bar{1}0]_{Al}|/3d[1\bar{1}0]_{Al} = |(0.828-0.858)|/0.858 \approx 3.4\%$ , whereas the two misfits along the  $[10\bar{1}0]_{\eta_1}$  and  $[11\bar{2}0]_{\eta_1}$  directions on the  $(0001)_{\eta_1}$  basal plane, respectively  $(\delta(p))_{[11\bar{2}0]}$  and  $(\delta(p))_{[10\bar{1}0]}$  for  $\eta_1$ ), were relatively large:  $\delta(p)_{[11\bar{2}0]} = |d[11\bar{2}0]_{\eta_1} - d[110]_{Al}|/d[110]_{Al} = |0.252-0.286|/0.286 \approx 11.8\%$ , and  $\delta(p)_{[10\bar{1}0]} = |d[10\bar{1}0]_{\eta_1} - d[001]_{Al}|/d[001]_{Al} = |(0.436-0.405)|/0.405 \approx 7.7\%$ , where  $a = 0.504$  nm and

**Fig. 6.** An  $\eta_1$  precipitate in the CAF Al alloy. (a) A HAADF-STEM image taken along the  $[110]_{\text{Al}} // [1\bar{2}10]_{\eta_1}$  zone axis showing its edge-on configuration and the rhombohedron and the flattened hexagonal units. (b) An enlarged image of the area indicated by the frame in (a). (c, d) Enlarged images of the area indicated by the frame in (b), showing a rhombohedral-like unit and a flattened hexagonal structure. Red, orange, and blue circles indicate Zn, Zn/Mg, and Mg atomic columns, respectively. (e) Intensity profile along the line **e** indicated in (d). (f) Intensity profile along the line **f** indicated in (d). (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

$c = 0.828$  nm for  $\eta_1$  precipitates [63]. Detailed schematic diagrams indicating the lattice misfits of  $\eta_1$  precipitates in three growth directions with respect to the Al matrix are provided in Supplementary Fig. 5 (Supplementary Material II). To sum up, the smaller lattice misfits in the  $[0001]\eta_1//[1\bar{1}0]_{\text{Al}}$  direction would be the preferential growth direction with respect to the  $[11\bar{2}0]\eta_1//[110]_{\text{Al}}$  and  $[10\bar{1}0]\eta_1//[001]_{\text{Al}}$  directions. Therefore, it can be confirmed that  $\eta_1$  would possess the rod-like morphology with the elongated axis along the  $[0001]\eta_1//[1\bar{1}0]_{\text{Al}}$  direction, instead of the plate-like morphology reported in previous investigations [7,11].

As indicated in Table 1, while previous investigations [7,11,12,45,48] have revealed the slight difference in the orientation relationships between  $\eta_1$  and  $\eta_9$  precipitates, few of these studies have looked at the morphology of  $\eta_9$ . The schematic diagrams of the lattice misfit calculations in three growth directions of  $\eta_9$  (i.e.,  $\delta(v)_{[0001]}$ ,  $\delta(p)_{[11\bar{2}0]}$ , and  $\delta(p)_{[10\bar{1}0]}$ ) are also portrayed in Supplementary Fig. 6 (Supplementary Material II). The misfit vertical to the  $(0001)\eta_9$  basal plane,  $\delta(v)_{[0001]}$ , was  $|d[0001]\eta_9 - 3d[1\bar{1}0]_{\text{Al}}|/3d[1\bar{1}0]_{\text{Al}} = |0.828 - 0.858|/0.858 \approx 3.4\%$ , and the two misfits along the  $[10\bar{1}0]\eta_9$  and  $[11\bar{2}0]\eta_9$  directions on the  $(0001)\eta_9$  basal plane were  $\delta(p)_{[11\bar{2}0]} = |3d[11\bar{2}0]\eta_9 - 2d[001]_{\text{Al}}|/2d[001]_{\text{Al}} = |0.756 - 0.810|/0.810 \approx 6.7\%$ , and  $\delta(p)_{[10\bar{1}0]} = |2d[10\bar{1}0]\eta_9 - 3d[110]_{\text{Al}}|/3d[110]_{\text{Al}} = |0.873 - 0.858|/0.858 \approx 1.7\%$ , where  $a = 0.504$  nm and  $c = 0.828$  nm for  $\eta_9$  precipitates [63]. For this case, it can be assumed that the higher growth rate in the  $[10\bar{1}0]\eta_9$  direction would promote the smaller growth rate in the  $[11\bar{2}0]\eta_9$  direction on the  $(0001)\eta_9$  basal plane. Therefore, all three growth rates with respect to the  $(0001)\eta_9$  basal plane would be nearly equal, thereby resulting in the hexagonal prism morphology of the  $\eta_9$  precipitate. However, owing to the small volume fraction of  $\eta_9$  [11,12,16,45], its morphology and atomic structure are difficult to confirm by TEM/STEM micrographs.

Here, a special illustration comparing the atomic structures of  $\eta_1$  and  $\eta_9$  is presented in Fig. 7. Cs-corrected HR-STEM images along the  $[110]_{\text{Al}}$  zone axis show that the edge-on configurations of  $\eta_1$  and  $\eta_9$  on the  $(00\bar{2})_{\text{Al}}$  planes (Figs. 7a and b) possess similar structures, namely, the stacking faults (the yellow arrows in Figs. 7a and b) separating two specific atomic arrays. In Fig. 7a, the edge-on configuration of  $\eta_1$ , the different orientations and the continuous connections of flattened hexagonal arrays are totally distinct from those of the typical  $\text{Mg}_4\text{Zn}_7$  structures [51,52,54]. In Fig. 7b, the edge-on configuration of  $\eta_9$  reveals that its central part appears to be composed of the segregated Zn-column layers with the higher Z-contrast, and apart from the centre, it has more closely-packed atomic arrays of Mg and Zn/Mg atomic columns. Between them, blurred stacking faults composed of Mg or vacancies appear to be exist. Furthermore, the higher averaged Z-contrast of  $\eta_9$  than of  $\eta_1$  probably implies that the edge-on configuration of  $\eta_9$  with a hexagonal prism morphology possessed a larger amount of atomic columns (i.e., a higher thickness parallel to the zone axis) than that of  $\eta_1$  with a rod-like morphology. For more positive identification of  $\eta_1$  and  $\eta_9$ , the individual FFT diffractograms and simulated patterns were applied, as presented in Figs. 7c and e for  $\eta_1$ , and 7d and 7f for  $\eta_9$ , respectively. The  $10\bar{1}0\eta_1$  and  $0002\eta_1$  poles were parallel to the  $002_{\text{Al}}$  and  $2\bar{2}0_{\text{Al}}$  poles, respectively, along the  $[1\bar{2}10]\eta_1//[110]_{\text{Al}}$  zone axis. On the other hand, the  $10\bar{1}0\eta_9$  and  $0002\eta_9$  poles were parallel to the  $2\bar{2}0_{\text{Al}}$  and  $002_{\text{Al}}$  poles, respectively, along the  $[1\bar{1}00]\eta_9//[110]_{\text{Al}}$  zone axis.

Fig. 8a shows an HR-HAADF STEM image of an  $\eta$ -precipitate observed along the  $[110]_{\text{Al}}$  zone axis. It might be the first HR image taken along the  $[0001]\eta$  axis and exhibits the hexagonal stacking configuration of a  $\text{MgZn}_2$  structure. This atomic array is similar to

that of Q phases with the hexagonal unit cell, observed along the  $[001]_{\text{Al}}//[0001]_{\text{Q}}$  zone axis in the Al-Mg-Si-Cu aluminium alloys [77,82]. Fig. 8b shows an enlarged image of the area indicated by the frame in Fig. 8a, and Figs. 8c and d show the FFT diffractogram from Fig. 8a and the simulated ED spot obtained using  $\text{MgZn}_2$ , respectively. The image in Fig. 8a reveals the hexagonal morphology of the precipitate, which exhibits the  $\{\bar{1}2\bar{1}0\}$  habit planes. The  $\{0001\}$  planes that are the surfaces of this specimen may also be its habit planes. In addition, this precipitate may be regarded as an  $\eta_4$ -type, for it seems to have the orientation relationship of the precipitate with the Al matrix such that  $(0001)\eta_4// (110)_{\text{Al}}$  and  $[\bar{1}2\bar{1}0]\eta_4//[\bar{1}\bar{1}1]_{\text{Al}}$ , as indicated in Table 1. As seen in Figs. 8c and d, however, the  $20\bar{2}0\eta$  and  $0\bar{2}20\eta$  poles are not parallel to the  $1\bar{1}1_{\text{Al}}$  and  $\bar{1}11_{\text{Al}}$  poles, respectively, but the  $2\bar{2}00\eta$  pole is exactly parallel to the  $00\bar{2}_{\text{Al}}$  pole. This can be recognized in Fig. 8a, where the  $(1\bar{1}00)\eta$  facet is parallel to the  $(002)_{\text{Al}}$  plane (see the red arrows), but the  $(20\bar{2}0)\eta$  and  $(0\bar{2}20)\eta$  facets are not parallel to the Al lattice fringes on the  $(1\bar{1}1)_{\text{Al}}$  and  $(\bar{1}11)_{\text{Al}}$  planes (see the blue arrows). Therefore, the orientation relation of  $\eta_4$  with the Al matrix has to change into  $(0001)\eta//[110]_{\text{Al}}$  and  $[1\bar{1}00]\eta//[001]_{\text{Al}}$ , or we have to name it as a new type of precipitate. Since we cannot identify the atomic structure of  $\eta_4$  reported in previous papers [2,7,11,12,14,16,18,37,45–47], we temporarily call this precipitate  $\eta_4'$ . Hence, the atomic-scale observation of the precipitates along the  $[0001]\eta$  axis allows us to determine the exact orientation of the precipitates with regard to the Al matrix, which is important to elucidate their growth mechanism.

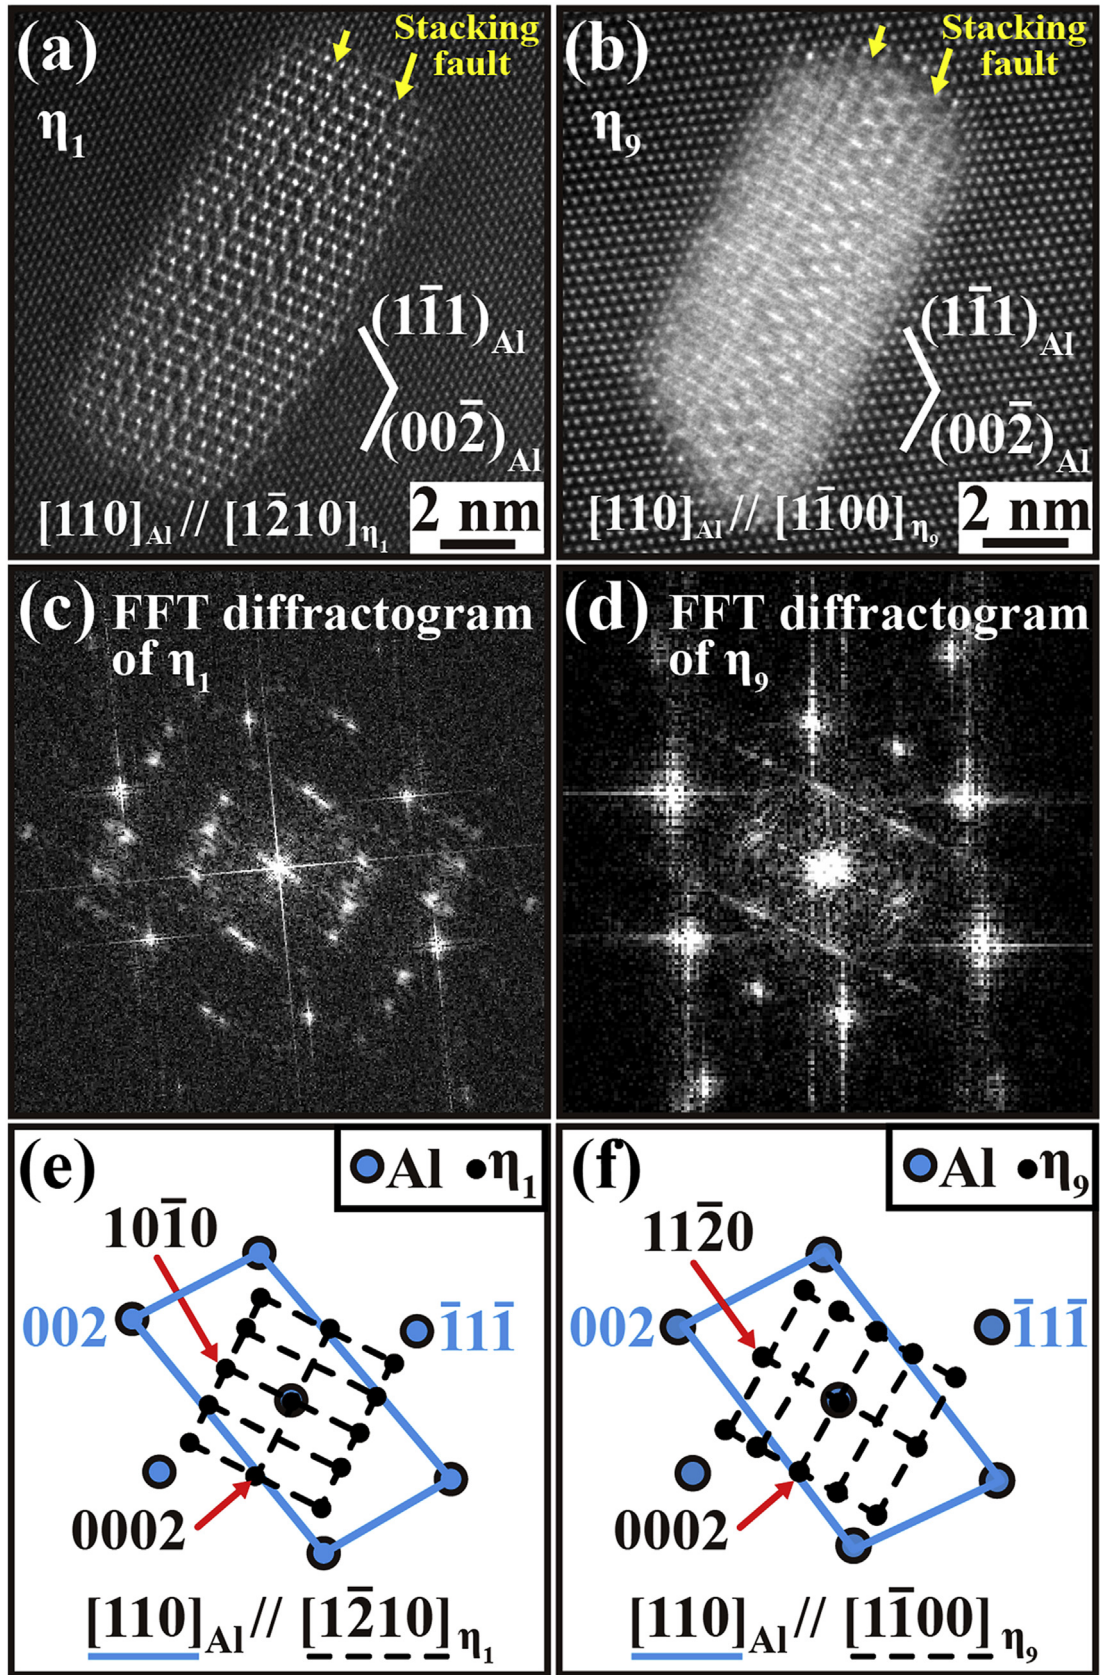

In Fig. 8a, a few  $(002)_{\text{Al}}$  lattices near the  $(2\bar{2}00)\eta_4'$  (and also the  $(2\bar{2}00)\eta_4'$ ) facets have much stronger and weaker contrasts (indicated by red arrows), which are respectively ascribed to Zn and Mg atoms that were segregated, migrated, and occupied Al-sites due to the chemical effect mentioned above. The  $\eta_4'$  precipitate develops by nucleation and lateral growth, being provided with these precursors of Zn and Mg. For the growth of edges of the layer, the similar replacement with Zn and Mg atoms was observed and is indicated by blue arrows in Fig. 8a. Thus, the layer-by-layer growth mechanism of the precipitates formed in these Al alloys has been supported by this observation.

Fig. 8e shows an enlarged and processed image of Fig. 8b, which was partially noise filtered, and emphasizes the Z contrast of atomic columns by means of inverse FFT reconstruction, using appropriately selected reflection spots from the FFT diffractogram (Fig. 8c). Fig. 8f shows the  $[0001]\eta$  projection of simulated atomic arrangements in the  $\eta$ - $\text{MgZn}_2$  crystal obtained by VASP. From the structure of  $\text{MgZn}_2$  [69], it turns out that the theoretical Z contrast ratio of red marked Zn columns, unmarked Zn columns, and Mg columns in Fig. 8e could be 900 (2 Zn): 450 (Zn): 244 (2 Mg)  $\approx 6 : 3 : 1$ . The observed image can clearly resolve the difference between Zn atom columns and Mg atom columns. The chemical compositions of every atomic column have yet to be analysed.

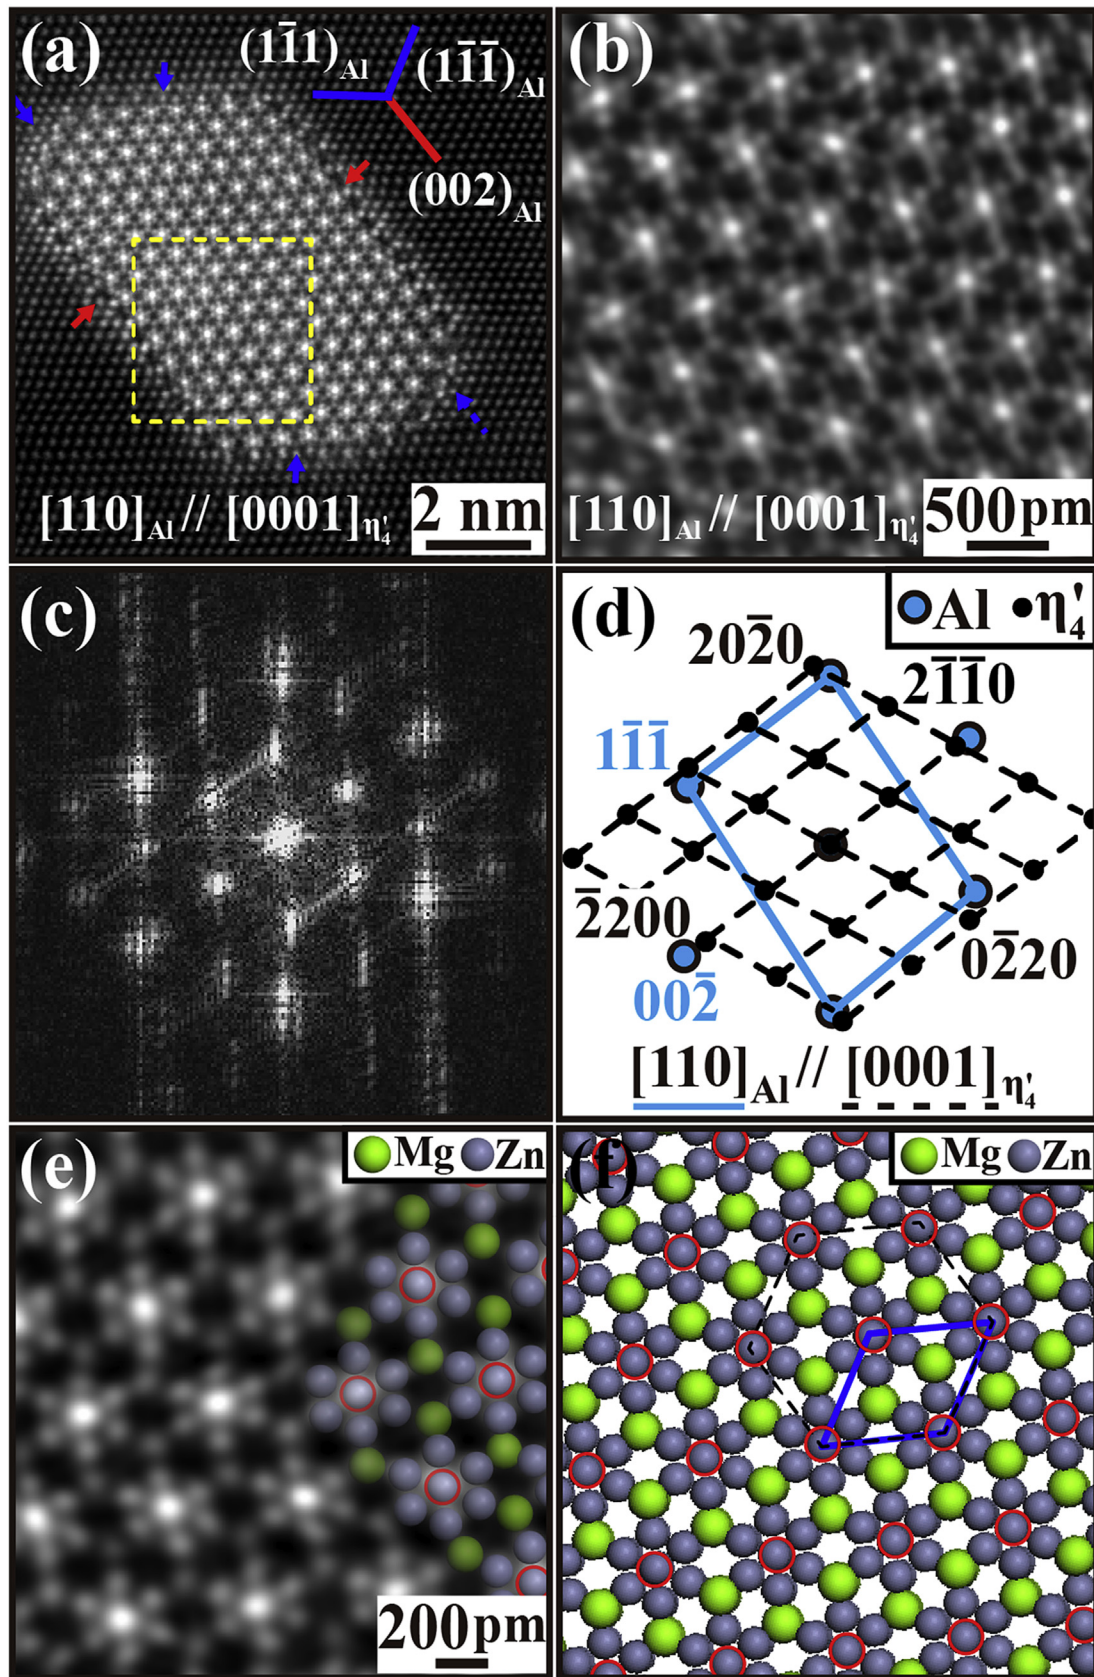

Basically all of the  $\eta$ -type precipitates have the structure of  $\text{MgZn}_2$  crystal, which was analyzed by Komura et al. [69]. Previously, Marioara [18] and Bendo et al. [11] indicated its atomic projection along the  $[10\bar{1}0]\eta$  and  $[11\bar{2}0]\eta$  zone axes in HAADF-STEM images. As mentioned above, eleven types of precipitates, named  $\eta_1$  to  $\eta_{11}$ , have been reported. In addition, we have identified another type of precipitate and named it  $\eta_4'$ , which was observed in the image along the  $[0001]\eta$  axis and presented a striking array of atoms. The differences among these 12 types of  $\eta$  precipitates are mainly ascribed to their orientation relationships with regard to the Al matrix, which lead to different morphologies (i.e., the shapes and habit planes), as shown in Table 1 and Fig. 1.

From this point of view, the following precipitate can be regarded as a new type of  $\eta$  precipitate. Figs. 9a and b show HR HADF-STEM images of an  $\eta$  precipitate possessing a zig-zag structure taken

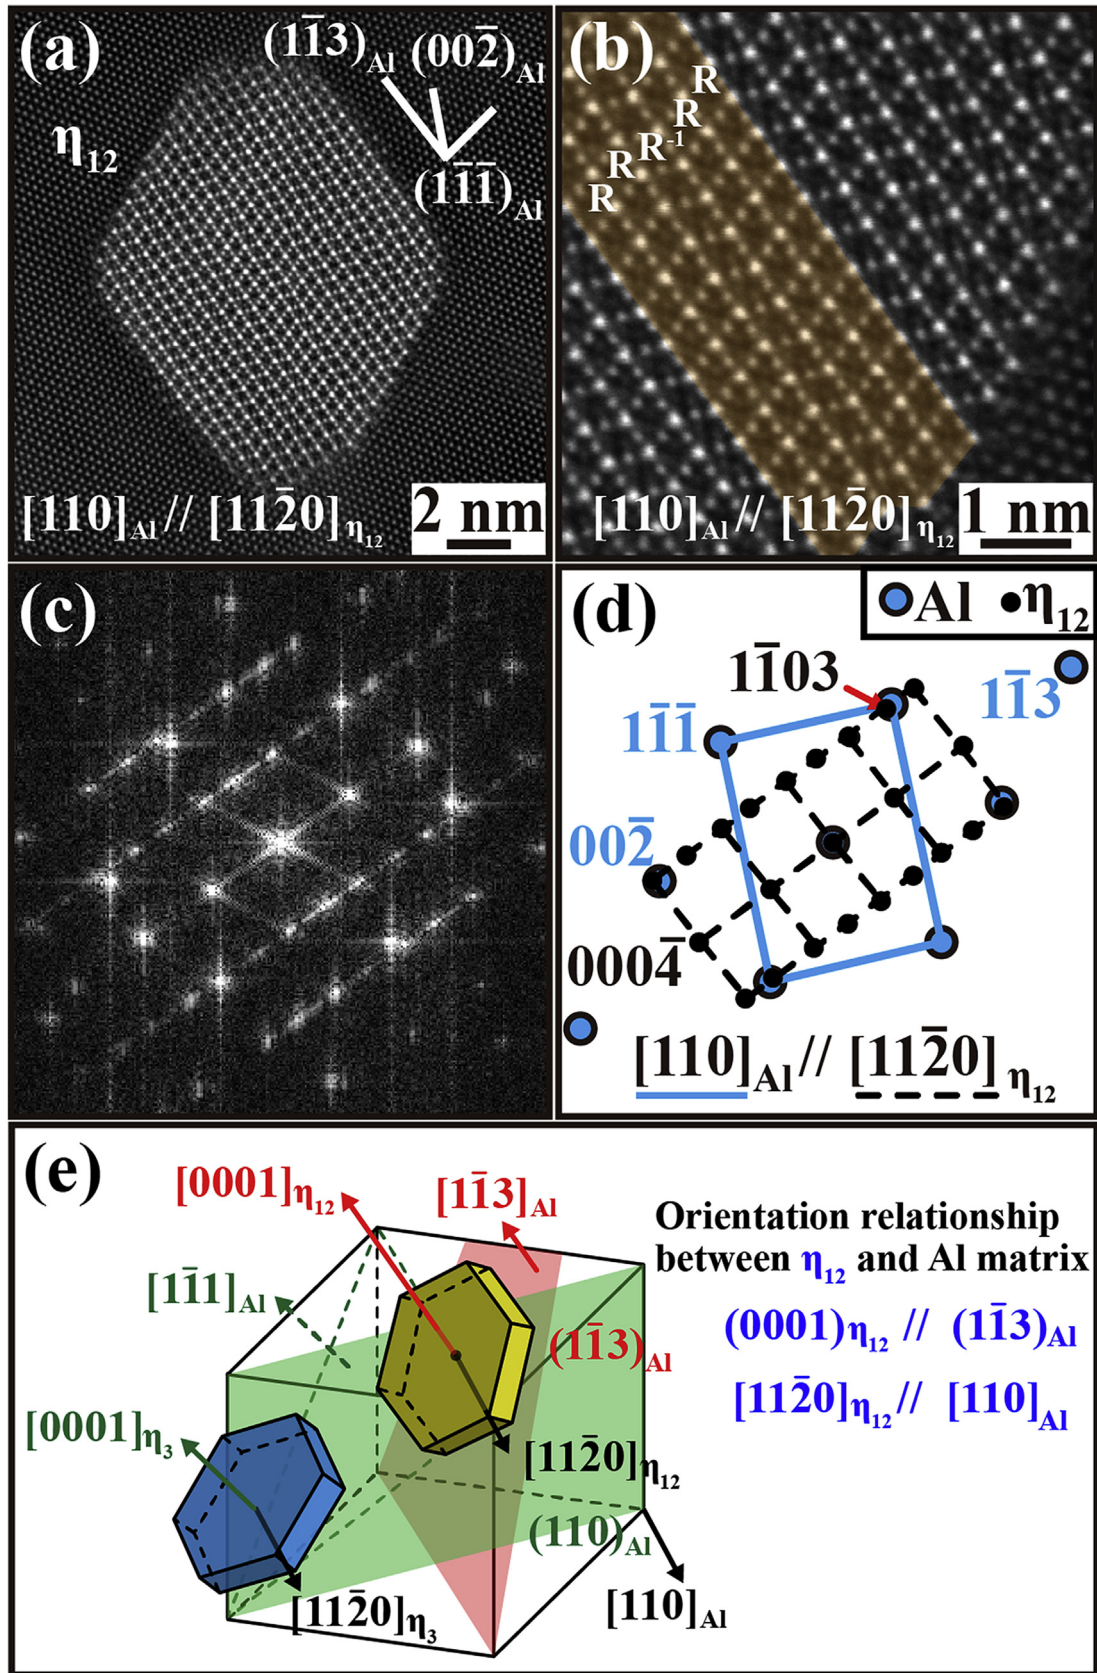

**Fig. 7.** HR-STEM images along the  $[110]_{Al} // [1\bar{2}10]_{\eta_1} // [1\bar{1}00]_{\eta_9}$  zone axis showing (a–b) the edge-on configuration of  $\eta_1$  and  $\eta_9$  on the  $(00\bar{2})_{Al}$  habit plane, respectively. (c, e) The FFT diffractogram and the simulated diffraction pattern of  $\eta_1$  with respect to its orientation relationship:  $(10\bar{1}0)_{\eta_1} // (001)_{Al}$ ,  $[0001]_{\eta_1} // [1\bar{1}0]_{Al}$ , and  $[1\bar{2}10]_{\eta_1} // [110]_{Al}$ . (d, f) The FFT diffractogram and the simulated diffraction pattern of  $\eta_9$  with respect to its orientation relationship:  $(11\bar{2}0)_{\eta_9} // (001)_{Al}$ ,  $[0001]_{\eta_9} // [1\bar{1}0]_{Al}$ , and  $[1\bar{1}00]_{\eta_9} // [110]_{Al}$ .

**Fig. 8.** (a) The (0001) HR-STEM image of an  $\eta$  precipitate in the CAF Al alloy taken along the  $[110]_{\text{Al}}/[0001]_{\eta'_4}$  zone axis showing its edge-on configuration of the  $(2\bar{2}00)_{\eta}$  plane on the  $(002)_{\text{Al}}$  plane. (b) An enlarged image of the area indicated by the frame in (a). (c) FFT diffractogram from (a). (d) Simulated ED pattern. (e) An enlarged configuration, processed image of part of (a), showing hexagonal stacking together with the structure model. (f) The structure of  $\text{MgZn}_2$  projected along the  $[110]_{\text{Al}}/[0001]_{\eta'_4}$  zone axis. The precipitate was named  $\eta'_4$  as it has a new orientation relationship of  $(0001)_{\eta'_4}/(110)_{\text{Al}}$  and  $[1\bar{1}00]_{\eta'_4}/[001]_{\text{Al}}$ .

**Fig. 9.** The new  $\eta_{12}$  precipitate in the CAF Al alloy. (a) A HAADF-STEM image taken along the  $[110]_{\text{Al}} // [11\bar{2}0]_{\eta_{12}}$  zone axis showing its edge-on configuration of the  $(0001)_{\eta_{12}}$  plane on the  $(1\bar{1}3)_{\text{Al}}$  plane. (b) An enlarged image of (a) showing the disordered rhombohedral stackings (i.e., the five-layer  $\text{RRR}^{-1}\text{RR}$  stackings highlighted in orange) laterally connected with the perfect  $\text{RR}^{-1}$  stackings. (c) FFT diffractogram of the whole area in (a). (d) Simulated ED pattern for the  $\eta_{12}$  precipitate, indicating a new orientation relationship of  $(0001)_{\eta_{12}} // (1\bar{1}3)_{\text{Al}}$  and  $[11\bar{2}0]_{\eta_{12}} // [110]_{\text{Al}}$ . (e) Schematic diagram indicating its morphology and the orientation relationship with respect to the Al. For comparison, those for  $\eta_3$  precipitate are added. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

along the  $[110]_{\text{Al}}$  zone axis. From its FFT diffractogram shown in Fig. 9c and the simulated ED pattern illustrated in Fig. 9d, its orientation relationship with the Al matrix was determined to be  $(0001)_{\eta} // (1\bar{1}3)_{\text{Al}}$  and  $[11\bar{2}0]_{\eta} // [110]_{\text{Al}}$ . Since this orientation relationship has not been reported for any  $\eta$ -type precipitates, we named this new type precipitate  $\eta_{12}$ . It can be regarded as an  $\eta_3$  precipitate that nucleates on the  $(0001)_{\eta} // (1\bar{1}3)_{\text{Al}}$  plane instead of on the  $(0001)_{\eta} // (1\bar{1}\bar{1})_{\text{Al}}$  plane of  $\eta_3$ , keeping the relation of  $[11\bar{2}0]_{\eta_{12}} // [11\bar{2}0]_{\eta_3} // [110]_{\text{Al}}$ , as seen in Fig. 9e. The growth behaviors such as the growth rate of the  $\eta_{12}$  precipitate would be different from that of  $\eta_3$ -type crystal grown on the close-packed  $(1\bar{1}\bar{1})_{\text{Al}}$  plane. In addition, Fig. 9b shows that the zig-zag  $R/R^{-1}$  stacking structure taken along the  $[11\bar{2}0]_{\eta_{12}}$  axis, similarly to that of  $\eta_2$ , as shown in Fig. 4. It can be found that in Figs. 9a and b, along the zone axis of  $[11\bar{2}0]_{\eta_{12}}$ , the disordered rhombohedral stackings, i.e., the five-layer  $RRR^{-1}RR$  stackings (highlighted in orange as shown in Fig. 9b), are laterally connected with the perfect  $RR^{-1}$  stackings. This stacking faults (i.e., the  $RRR^{-1}RR$ ) would not introduce the formation of flattened hexagonal arrays. This should not be recognized as the same with the characteristic of  $\text{Mg}_4\text{Zn}_7$  structures [51,52,54].

The structure of  $\text{Mg}_4\text{Zn}_7$  [51,52,54] supposedly involves with the formation or annihilation of vacancies and dislocations, leading to the change of lattice constants to accommodate the variation of interface energy [44], which would presumably be consistent with the alternations of the stacking sequences in the Laves phases, proposed by Komura et al. [26]. Alternatively, in the present work, vacancies and dislocations can be introduced by the layer-by-layer growth or coalescence of  $\eta$  crystals, changing both the atomic spacing and the electronic state between Zn and Mg solute atoms [21]. The formation of the flattened hexagonal units presumably occurs to reduce the impact of the changes, and under some circumstances these units possibly transform to the perfect rhombohedral units by the annihilation of their intrinsic defect structures. However, this mechanism is still unclear and needs to be confirmed.

#### 4. Conclusions

We have investigated the structures and the growth of  $\eta$ -type precipitates in ageing-treated AA7050 aluminium alloy by means of atomic-scale HAADF-STEM. Conclusively, all  $\eta$ -type precipitates have the approximate structure of  $\text{MgZn}_2$  crystal, and the differences among the 13 types of  $\eta$  reported so far are ascribed to the orientation relationships with regard to the Al matrix. The important findings from HAADF-STEM observations can be summarized as follows:

1. The  $\eta_2$ -type precipitates observed along the  $[10\bar{1}0]_{\eta_2} // [110]_{\text{Al}}$  zone axis grew with the  $(0001)_{\eta_2}$  habit plane parallel to the  $(1\bar{1}\bar{1})_{\text{Al}}$  plane. The regular variation of stacking layers along the basal plane (i.e., the sandwiched stacking structure) was confirmed as the projection of each atom column in the  $\eta$ - $\text{ZnMg}_2$ . The local composition fluctuation was detected in the precipitate as well as in the Al matrix as the difference of Z contrast among the equivalent atomic columns.
2. The  $\eta_2$ -type precipitates observed along the  $[1\bar{2}10]_{\eta_2} // [1\bar{1}2]_{\text{Al}}$  zone axis grew with the  $(0001)_{\eta_2}$  habit plane parallel to the  $(1\bar{1}\bar{1})_{\text{Al}}$  plane. It was revealed that the regular variation of stacking layers (i.e., the zig-zag stacking structure) was observed to have a sequence of ...  $RR^{-1}RR^{-1}RR^{-1}$  ... along the  $(10\bar{1}0)_{\eta_2}$  plane as the projection of the structure of the  $\eta$ - $\text{ZnMg}_2$ , where R and  $R^{-1}$  are different rhombohedral-like units. Stacking faults such as  $RR^{-1}R^{-1}R$  or  $R^{-1}RRR^{-1}$  were also observed. It was also confirmed in the image of  $\eta_1$ -type precipitates observed along the  $[1\bar{2}10]_{\eta_1} // [110]_{\text{Al}}$  zone axis that the defect layer composed of

flattened hexagons forms as an anti-phase phase boundary between the regular stacking layers. The atomic structures of the R unit and flattened hexagons, in particular the positions of Mg atoms, were determined.

3. Growth steps and strong Z contrast (indicating Z atoms) were observed on the habit plane and in the Al planes near the habit planes, respectively. This suggests that the  $\eta$  precipitates grow layer-by-layer, and this growth is supplied with precursors such as Zn, Cu, or Mg atoms. These solute atoms migrate and become segregated around the interface due to a kind of chemical effect caused by its higher lattice strain energy. The formation of the layer defects is presumably associated with an embryo of the layer growth mismatched in stacking order.
4. Precipitates grown by coalescence of two  $\eta_2$  particles were observed. The coalescence of crystals precipitated on the same  $(1\bar{1}\bar{1})_{\text{Al}}$  layers brought about a complicated boundary due to the difference in their stacking orders. The coalescence between crystals precipitated on the  $(1\bar{1}\bar{1})_{\text{Al}}$  and  $(1\bar{1}\bar{1})_{\text{Al}}$  layers led to a twin-like structure. It was also proposed that the anti-phase boundary in the  $\eta_1$  can be caused by coalescence of two  $\eta_1$  particles.
5. The morphologies of  $\eta_1$  and  $\eta_9$  precipitates can be estimated by the differences in the lattice misfits in three directions with respect to the  $(0001)_{\eta}$  basal plane. For  $\eta_1$ , the smaller lattice misfit vertical to the  $(0001)_{\eta_1}$  plane than the two misfits parallel to the  $(0001)_{\eta_1}$  plane results in the rod-like shape, and for  $\eta_9$ , the nearly-equal three lattice misfits lead to the hexagonal prism morphology. Furthermore, this is the first report of the atomic configuration of  $\eta_9$  possessing the sandwiched stacking layers intermitted by stacking faults, similar to the zig-zag atomic configuration embedding the flattened hexagonal faults of  $\eta_1$ .
6. Two new types of  $\eta$  precipitates have been recognized by their orientation relationships with regard to the Al matrix. One is  $\eta_4'$ , which can be distinguished from  $\eta_4$  in the  $(0001)_{\eta_4}$  image taken along the  $[110]_{\text{Al}}$  zone axis and exhibits the atomic configuration (i.e., the hexagonal stacking structure) of  $\text{MgZn}_2$  along  $[0001]_{\eta_4'}$ . Another is  $\eta_{12}$ , which can be observed with the  $(0001)_{\eta_{12}}$  habit plane parallel to the  $(1\bar{1}3)_{\text{Al}}$  plane in the  $[11\bar{2}0]_{\eta_{12}}$  image taken along the  $[110]_{\text{Al}}$  zone axis.
